The erosion glands—neoplastic glandular formations found in the erosions or catarrhal patches on the surface of the portio vaginalis—constitute unquestionably the fons et origo of a large majority of the carcinomatous affections in this location. The minute changes which result in a transformation of an erosion, which is generally considered a very insignificant pathological entity, but which Ruge and Veit regard as a not always simple and unsuspicious process, need not be discussed at length in these pages, which are concerned more particularly with the clinical aspect of cancer of the cervix. Suffice it to say that the various stages of change and development have been fully recognized and described, and the etiological significance of childbirth, and the resulting lesions and pathological states of the neck of the uterus, at once, therefore, become obvious.

One other variety of cancer of the portio vaginalis remains to be mentioned, namely: that which, beginning in a proliferation of the connective tissue beneath the epithelial investment of this part of the neck, finally breaks through and gives rise to a cauliflower-like growth similar to that previously described.

In the cervix, as distinguished from the portio vaginalis—a distinction which is of considerable importance both from a pathological and clinical stand-point—carcinoma may also develop, either from the connective tissue underneath the mucous membrane of the cervical canal, or from glandular structures. In the first of these two forms a cancerous nodule appears in the substance of the cervix beneath the sound mucous membrane. The disease may subsequently extend upward into the lower segment of the corpus, downward into the portio vaginalis, outward into the parametrium, but finally breaks through the mucosa of the cervical canal, leaving an ulcerating crater often of considerable depth. The malignant process does not, however, tend to involve the mucous lining of the cervical canal, nor does it readily pass beyond the limits of either the internal or the external os.

In the second variety, akin to the malignant adenoma of the corpus, the cervical glands proliferate enormously, invading the substance of the cervix, obliterating its tissue framework, and extending thence in various directions.

Or again, in a third type, the cylindrical epithelium clothing the cervical mucosa proliferates considerably, forming an epidermoidal stratum similar to cancer of the skin, epithelial processes from which subsequently invade and destroy the underlying stroma.

Hofmeier shows with what frequency the different portions of the neck of the uterus are primarily affected by carcinoma: In 812 cases of cancer of this organ the portio vaginalis was first attacked in 236, and the cervix in 181, while in 367 no mention pertinent to this point is made.

In the early advancement of these different forms of cancer, the various modes of progression already pointed out are pursued, but when the disease, whatever its origin, reaches a certain point, all boundaries are swept away, and it devastates the environing tissues on all sides. Not only, on the one hand, does ulceration destroy all anatomical barriers opposed to it, but the numerous lymphatic vessels of the pelvis gather up and hurry off the germs of infection to deposit them far and wide, where they in turn become fresh foci of disease. Thus the vagina becomes involved through direct contiguity of tissue, and the vesico-vaginal, and more rarely the recto-vaginal, septum crumbles away and fistulæ are formed. The ureters may be compressed by cancerous infiltration in the bladder-wall near their points of exit, or by the infiltrated connective tissue which they traverse, or, finally, by deposits in their own structure; from any or all of which simple or double hydronephrosis results, leading in the latter instance to grave uræmic manifestations that may be suddenly mitigated by the breaking down of the affected areas. In a large number of instances the kidneys suffer other grave structural alterations, and exhibit various forms of degeneration in their secreting apparatus, and not infrequently contain purulent collections.

The rectum, aside from the loss of a portion of its wall, becomes inflamed, as do also the uninfected portions of the bladder and vagina.

Should gangrene extend upward, the corpus uteri gradually melts away until it forms simply a suppurating shell, or indeed becomes absolutely destroyed.

The pelvic connective tissue, at first inflamed and subsequently infiltrated with carcinomatous disease, becomes dense, resistant, and inelastic, so that the functions of the bladder and rectum may be markedly crippled long before these structures are themselves directly attacked.

It is not surprising, what with the well-known close anatomical relations of the pelvic contents and the abundant means of intercommunication, that the peritoneum ere long should participate in the ever-advancing morbid process. That portion of the peritoneum in nearest proximity to the disease becomes inflamed and adhesions are formed, which to a certain extent are conservative and protect the general peritoneal cavity. Nevertheless, the products of decomposition may be carried upward into, or burst through, these barriers, and the patient will rapidly succumb to an acute, general, purulent peritonitis. Diffuse cancer of the peritoneum is rarely encountered.

The pelvic glands are frequently enlarged and transformed into cancerous masses that subsequently soften and break down, and the ovaries, with which the former are often confused, become implicated in a certain proportion of cases.

The formation of thrombi and emboli is facilitated by the condition of the blood and by the feebleness of the circulation, and is directly induced by the compression or invasion of an artery or vein—usually the latter—by a portion of the carcinomatous growth. This, with the coagulum formed about it, is swept away as an embolus.

Metastatic deposits of cancer likewise may occur in any of the near or remote viscera.

It is, of course, not to be supposed that these morbid processes are to be observed singly. In any neglected case of carcinoma of the neck of the uterus many, and, indeed, most, of them are exhibited at some time during its course, and the pathological picture usually presented is one of great diversity.

At this point it may be permitted to introduce some numerical evidence of the frequency with which the various organs and tissues of the body become involved in the cancerous degeneration beginning in the cervix uteri.

According to Gusserow, who details the results of Blau's investigations as well as his own, in 311 cases of carcinoma there was infiltration of the bladder in 128 and vesico-vaginal fistula in 56. In 93 cases there was pyelonephritis in 10, parenchymatous nephritis in 4, atrophy of the kidney in 7, amyloid degeneration in 4, cloudy swelling of the uriniferous tubules in 2, and metastatic deposits in the kidney in 5. In 282 instances of this same affection the rectum was invaded 53 times and recto-vaginal fistula developed in 27. Wagner found the rectum involved in 32 of 171 cases.

It would be inexpedient to finally dismiss the topic of the morbid anatomy of carcinoma of the neck of the uterus without making some allusion to the work recently performed in Germany by Abel, Fränkel, Thiem, Saurenhaus, Orthmann, Eckart, and others, in determining the condition of the corporeal endometrium in cases of this character where the malignant degeneration is confined to the cervix or portio vaginalis. These investigations, if they have accomplished nothing else, have proved very conclusively the origin of a large part of the bleeding which occurs before the period of ulceration, and, even without the confirmation of Abel's views, have exercised considerable influence upon the selection of operation.

K. Abel, in examining seven uteri removed by Landau for carcinomatous degeneration limited to the cervix or portio vaginalis, found that the mucous membrane lining the body was the seat of very pronounced pathological changes, which in five of the seven, owing to the presence and peculiar arrangement of round or spindle cells and the absence of any signs of inflammatory reaction, could only be interpreted, he asserts, as sarcomatous degeneration of the endometrium, which, in three of the cases, was quite far advanced. In the remaining two cases there was marked inflammation of the mucosa, which involved both the glands and the interglandular substance, but nothing pointing to the existence of a new growth could be discovered.

Investigations were at once instituted in various directions to ascertain the correctness of these opinions; for if sarcoma of the corporeal endometrium occurs as frequently along with cancer of the neck as Abel would indicate, then the survival of so many women after supravaginal amputation of the cervix in the past would be a matter of surprise, and for the future total extirpation would become the only justifiable, because the only radical, operation in this affection.

Fränkel examined 6 specimens, 4 removed by total extirpation during life, and 2 from patients dead of inoperable carcinoma; Thiem, 9 specimens from living subjects; Saurenhaus, 50; Orthmann, 10; and Eckart, 10, making in all 85 uteri, the condition of whose lining membrane was studied. The result was practically identical in every instance. The utricular glands and interglandular structures, now one, now the other, oftenest both, were found to exhibit those changes which are commonly regarded as characteristic of chronic endometritis. The microscopical sections showed practically the same pictures as Abel had observed, but the interpretations of these findings were unanimously opposed to his.

It may be safely maintained, then, not only upon the authority of those already mentioned, but upon that of others, notably Ruge, who have expressed very decided opinions in this matter, that in cancerous degeneration limited to the cervix uteri or portio vaginalis the mucous membrane of the body of the uterus exhibits in nearly every instance very pronounced pathological alterations—alterations which are quite typical of "glandular hypertrophic" or hyperplastic endometritis, and again of endometritis interstitialis, with a tendency to the development of vessels in the mucous membrane," and, therefore, of various well-known morbid processes which are constantly seen, and may be called forth by a variety of causative agents; but the coincident occurrence of sarcoma of the endometrium is as yet very far from being proven.

ETIOLOGY.—In the discussion of epithelioma of the cervix, age is a factor of etiological significance which at once claims our attention. In spite of the alleged inconsistency and unreliability of statistical evidence, in the present instance it will be admitted, I believe, that such evidence is everywhere in accord. It is true that the disease has been observed in children of tender years, in adolescents, in early womanhood, and, again, in the very aged; but nevertheless, it is universally acknowledged that women at or about the time of the climacteric are most subject to the ravages of this loathsome affection. Thus Gusserow's analysis of 3,385 cases of cancer of the uterus shows that at seventeen years there was 1 case; at nineteen, 1 case; between twenty and thirty there were 114 cases; between thirty and forty, 770 cases; between forty and fifty, 1,169 cases; between fifty and sixty, 856 cases; between sixty and seventy, 340 cases; and over seventy, 134 cases.

The results of Hofmeier's investigations are in agreement with the foregoing, for he found that the average age in carcinoma of the portio vaginalis was forty-two years, and in carcinoma of the cervix forty-seven years.

Ganghofner, however, has recently reported an instance of carcinoma of the portio vaginalis occurring in a girl aged eight; Eckart, one of carcinoma of the cervix in a girl aged nineteen; and Schauta, from Späth's clinic, has described a tumor of the vaginal portion in a girl of seventeen, which showed the transition form between adenoma and carcinoma.

Several factors, doubtless, contribute to the increased prevalence of uterine cancer at the time of the change of life. With advancing years there is a greater tendency to retrograde tissue-metamorphosis throughout the whole human organism, and, locally, the effect of the vascular alterations incident to a general readjustment of the blood-current is of unquestionable etiological importance.

With regard to heredity as a predisposing cause of cancer of the cervix, or, indeed, of any other portion of the body, it is safe to say that we know next to nothing. Whatever information bearing upon this point is to be obtained from hospital patients is eminently untrustworthy, and it may be justly questioned whether, with the prevailing ignorance of disease among even the more intelligent of the laity, the evidence obtained from them is of any scientific value.

Occasionally, it is true, we are startled by such an incident as, for example, is recorded by Broca, where everyone of four daughters and ten grandchildren of a woman who died of cancer of the breast were themselves the subjects of carcinomatous affections. Barker also mentions a family of which eight members succumbed to this disease, and, more recently, Guttman records three cases of cancer of the uterus among seven sisters; but in the first instance it is distinctly stated that there was no history of malignant disease among the immediate ancestors, and in the second the matter is not referred to. Indeed, all the evidence that has been accumulated, if it proves anything, goes to show that the importance of heredity in this connection has been much exaggerated.

From Gusserow's statistics, founded upon 1,203 cases of cancer of the uterus seen in the private practice of himself and others, it would appear that in only 7.8 per cent. could any account of the previous existence of this disease be obtained, and no recent authority records a higher proportion than this. Such a small percentage can hardly be regarded as more than a coincidence.

It has been maintained that cancer of the uterus is less often met with among the whites of this country than among those of the same race living in Europe, and, further, that in America the negroes are not so frequently affected with this disease as the whites. Emmet states that he has known but a single negro woman, and she a mulatto, who had cancer of the uterus; and, according to Chisolm's statistics, carcinoma is more than twice as frequent among the white population than among the black. I have found in my own clinic at the Central Dispensary in Washington, D. C., that cancer of the cervix occurs on an average in 1.2 per cent. of all negroes, and in 0.6 per cent. of all whites examined; and in estimating these proportions I have included only those cases where the diagnosis of cancer admitted of not the least atom of doubt.

Excluding constitution, temperament, occupation, and the social state as etiological factors of doubtful import, we are next confronted with a series of associated conditions deserving of the utmost consideration. It has been proven beyond question that cancer of the uterus is far more common in fertile than in sterile women; and, furthermore, that those who are the subjects of this affection have borne a larger number of children than is usual during married life.

Thus among 1,540 cases collected by Gusserow, including some of his own, only 121 were sterile; in 812 mentioned by Hofmeir but 39 were without offspring; and in 55 cases in Reamy's practice there was 1 single and without children, and 1 married and sterile. While, according to the first of these authorities, in Prussia every married woman has, on an average, 4.6, in England 4.2, and in France 3.4 children, the proportion in 3,025 cases collected by himself was 5.1 children for each mother. Hofmeir reports that among 849 fertile women with cancer of the uterus, observed in the Berlin Polyclinic and Schroeder's private practice, 106 had had one child, 667 had borne on an average 5.8 children, and 76 had been pregnant more than ten times. Winckel's figures are quite as convincing, for in 130 cases of uterine carcinoma ten per cent. were I.-paræ, 40.8 per cent. were II.–V.-paræ, and 49.2 per cent. were VI.–XXVI.-paræ. In the 55 cases heretofore referred to as mentioned by Reamy, 53 had had 217 pregnancies.

Now, with these facts in mind, it is very easy to proceed a step further to the point from which parturient injuries of the cervix and their pathological sequences are to be regarded as causative agents of malignant disease of the most pronounced importance. Emmet's views upon this matter are well known, and in them he is supported by Mundé, Goodell, Breisky, and others; but it is quite certain that while these latter may believe that "the occurrence of this form of malignant disease in a woman who has never been impregnated must be exceedingly rare," yet few are prepared to state, with Emmet, that they have "never known a woman to have any form of epithelial cancer of the uterus unless she has at some time been impregnated." Cervical catarrh, ectropium, erosions, and neoplastic glandular formations are processes or conditions which lead to, and, indeed, are often undistinguishable from actual carcinomatous disease; and while such a pathological picture may be presented by the vaginal portion of a virgin, it is in parous women that we are accustomed to see them, with or without appreciable laceration of tissue, most often and in their most pronounced forms. Nevertheless, there are certain links in this chain of argument which are wanting to make it perfect. While it is of service to know that cancer of the cervix is most frequently encountered in those who have been many times pregnant —and it is better to adopt this phrase, for many of the pregnancies in the foregoing enumeration of cases terminated abnormally early—yet it is more with the character of the ensuing labors than with their number that we are interested; and though, personally, we may be convinced of the causative importance of injuries of the cervix uteri and their pathological accompaniments and results in the development of epithelial cancer, yet we do not have at this time adequate ground for making broad generalizations. Convincing evidence can alone be furnished by a series of extended observations like those of Wells in Mundé's practice, by which it was shown that more than a third of a given number of cases of carcinoma of the cervix were known to have previously suffered cervical tears. Spanton and others have seen epithelioma springing up in a cervical rent.

The belief of Emmet that cancer of the cervix is encountered more often in the well-to-do than in the poorer classes of society is in accordance with his own, and the generally entertained opinion, that lacerations of the cervix occur no less often in the former than in the latter. That such lesions may be observed with greater frequency among the poor is doubtless true, and the reasons for this I have elsewhere attempted to point out.

SYMPTOMATOLOGY, PROGRESS, AND RESULTS.—Of all the diseases which may afflict womankind, nowhere is early recognition more important than in carcinomatous affections of the cervix uteri. In many of her ills the morbid state throws out sundry hints, warnings of approaching danger, that serve to put her on her guard and lead her to seek relief while yet it may be obtained. Here it is otherwise; nature is less beneficent, and the appearance of symptoms too often leads but to the discovery of an advanced stage of this horrible affection, and predicates the abandonment of hope. The signs of the stages through which it has already passed are indefinite, if not altogether negative. Of such as exist we know little. In spite of what has been taught us in recent years and what we ourselves see, we still cling tenaciously to that tradition which makes cancer of the uterus, whatever be its kind or degree of progress, indissolubly associated with hæmorrhage, with foul discharge, and with agonizing pain. But, as H. Meyer puts it, he who first suspects cancer when such symptoms are present will never find it in its early stages.

Of all the affections which a physician may be called upon to recognize and treat, cancer of the cervix is one with whose earliest manifestations he should have the most intimate acquaintance. Discovered in time it is amenable to cure; neglected, death is inevitable.

Considering this one disease, how great becomes the responsibility of the general practitioner, of whom, naturally, advice is first sought, and how great is the need of new light upon the symptomatology of its incipient stages. As has been already said, if there be any disturbances which occur during the early life-history of cancerous disease of the cervix uteri we are unacquainted with their nature, and in the existing state of our knowledge we are obliged to fall back upon those symptoms which become manifest, with rare exceptions, only when ulcerative disorganization of the infiltrated tissues has begun.

Bleeding probably first attracts the attention of an observant woman, but it fails in the vast majority of instances to excite more than a passing curiosity as to its origin. If her suspicions are aroused they are quickly set at rest by the explanations and asseverations of her female friends. This bleeding, it should be at once understood, is not hæmorrhage. It is small in quantity, usually not exceeding a drop or two, occurs quite independently of menstruation, and usually ensues upon traumatism, therefore following coitus or, as in a case of my own, the introduction of the tip of a syringe into the vagina. Unusually pronounced physiological excursions of the uterus, such as are induced by certain forced or sudden movements of the body, straining at stool, etc., may also, through traumatism, bring about the same result. This "show" could only occur were the disease seated upon the portio vaginalis, and is far from distinctive of malignancy, as is well known. In the benign papillary erosion or catarrhal patch, and in the primary stages of the epithelioma developed therefrom, before ulceration has taken place, local injuries will be followed by rupture of some of the thin-walled and dilated vessels so superficial as to be exposed to every injury, and bleeding will result.

Again, it is with menorrhagia or metrorrhagia that the disease first manifests itself; but this is due, as Coe and Eckart have pointed out, to the accompanying endometritis already fully described in these pages.

Irregular but not profuse hæmorrhages occurring before, at the time of, or after the establishment of the menopause, are usually regarded as quite typical of this time of life, and when they take place in a woman with cancer of the uterus both she and her medical attendant may be lulled into a feeling of fancied security, from which sooner or later there is to be a rude awakening. If ever during life, at or about the climacteric period the slightest disturbance must be viewed with the utmost suspicion and subjected to the most critical investigation. These "atypical" hæmorrhages, whatever be their frequency or quantity, are pathological and must be so regarded.

With the advance of the cancerous process, the discharge of blood becomes a more pronounced symptom.

Heretofore that which has occurred has been largely the result of general uterine hyperæmia. Now the infiltrated tissues press upon the veins, diminish the amount of the return current, while blood-pressure is decidedly increased, and vessel-rupture takes place. The vascular and luxuriant cauliflower excrescences projecting into the vagina, should the disease take that form, likewise give rise to considerable loss of blood; and when by ulceration the wall of some vessel of relatively large size is opened, the hæmorrhage may be profuse and exhausting. Usually, however, when the carcinomatous affection is in its incipiency, and occasionally when ulceration has far advanced, there may be nothing but a thin, pinkish discharge from the genitals. Indeed, although bleeding may be said to be the earliest and most constant symptom of cancer of the cervix, it is uncommon to observe pronounced hæmorrhage, and death from such cause is extremely rare.

Discharges of various kinds other than blood are likewise almost invariable accompaniments of all of the different forms of the disease under discussion. At first there is no discharge, or a slight, thin, inodorous, serous flow may appear, which, like the bleeding occurring at the same time, may simply result from the hyperæmic condition of the corporeal endometrium, may be an accompaniment of an antecedent erosion, or may follow from the incipient pathological changes at the site of the future new growth. This discharge may be quite clear, or pink, or streaked with blood, or reddish from blood-admixture. After ulceration has begun it becomes distinctly purulent, and in the more advanced stages of the affection, when the neoplasm has become gangrenous, it assumes a dirty yellowish or reddish-brown color, becomes mixed with shreds of disorganized tissue, and exhales an odor so foul and penetrating that it makes the sufferer a horror to herself and poisons the atmosphere around her.

There is no pain distinctive of commencing malignant disease of the cervix. As Coe has suggested: "It should be remembered that the patient has already an extensive laceration of the cervix of long standing, and probably the remains of former perimetritic inflammation, the symptoms of which would mask any fresh ones produced by the incipient cancer." He himself has observed sciatica in several instances of beginning epithelioma. Whatever vague pains in the back or pelvis occur at this time can usually be ascribed to peritoneal irritation. Later, when the cancerous infiltration has invaded the parametrium, tearing, dragging, or lancinating pain is complained of, which owes its origin to pressure or traction exerted upon the nerve-filaments or trunks ramifying in this locality. Should the disease extend upward so as to invade the body of the uterus, pain from the same cause may be a pronounced symptom, as also when the vaginal walls become involved.

It may be said, indeed, that there is no suffering experienced by the patient as long as the disease is confined to the cervix uteri, but that with infiltration of surrounding tissues pain begins, to subside often with the advance of ulceration.

The cancerous cachexia is to be observed only when the disease has made considerable advancement. Until this time the patient may appear to be robust and well. Ultimately the appetite fails, there are gastric catarrh, perhaps vomiting, and constipation. In consequence digestion, assimilation, and nutrition become seriously impaired. Anæmia and the absorption of the products of decomposition still further deteriorate the general health, until, finally, the unfortunate woman, to use the words of Lusk, becomes wan, yellow, and wrinkled, and wears an aspect of profound suffering.

Toward the end many complications arise which still further increase the distress of the patient and hasten the final issue. Thus uræmia, œdema of the lower extremities, cystitis, proctitis, vesico- or recto-vaginal fistulæ, and intolerable pruritus, are frequent concomitants of the further extension of the disease. In spite of the amount of sloughing tissue and the imperfect escape of the products of decomposition, septicæmia and pyæmia are not common, for the infiltrated and inflamed areas beyond the region of gangrene go far to diminish the absorption which is favored in every other way.

It is next to impossible to determine with any accuracy the duration of life in a case of epithelioma of the cervix. From what has been already said it is evident that the clinical history of the disease in its incipiency is practically unknown to us, and our only method of determining its duration is to count from the date of the appearance of the first pronounced symptoms, a time usually synchronous not with the beginning but with an advanced stage of the disease. It is commonly estimated that from this period until death, in instances where no treatment, or only such as is palliative is instituted, not more than one year and a half elapses, although a fatal termination often occurs sooner, and occasionally life is more prolonged.

That death is the inevitable result in neglected cases is a well-established fact, and the reported instances of so-called spontaneous cure are neither sufficiently numerous nor sufficiently conclusive to warrant a different belief.

In a disease like cancer of the cervix, which is attended by so many and such wide-spread complications, it is not surprising that the possible causes of death are numerous. In 155 cases of this affection, according to Gusserow, death occurred 38 times from some form of peritonitis. Among the 93 fatal cases recorded by Blau, the final issue was due in 48 to marasmus, in 11 to pneumonia, in 3 to pleurisy, in 3 to embolism of the pulmonary artery, in 1 to pyelo-phlebitis, fatty degeneration of the heart, pulmonary gangrene, and pyelo-nephritis, respectively. In the 62 cases from Seyfert's clinic, mentioned by Säxinger, there were 9 deaths from pyæmia, 5 from amyloid degeneration of the abdominal glands, 3 from œdema of the lungs, 3 from dysentery, and 28 from uræmia.

It is next to impossible in any given case to ascribe the death of the patient to any one cause. The unfortunate is set upon on all sides by a host of enemies against which it is impossible to cope. Digestion, assimilation, nutrition, secretion and excretion, respiration and circulation —all the functions whose proper performance is necessary to health—in multifarious combinations become interfered with and gradually overwhelmed, until finally death comes as a welcome release to the tortured and exhausted sufferer.

DIAGNOSIS.—The importance of the early recognition of cancer of the neck of the uterus and the general ineffectiveness of the means in our possession to attain this end have already been referred to. The subjective symptomatology of all stages of this disease has likewise been noticed. Those forms of cancer which begin either upon the outer aspect of the portio vaginalis, or in the connective tissue immediately beneath the mucous membrane covering it, are most likely to be discovered by physical examination while yet in their incipiency.

It should be remembered that the neck of the uterus probably already exhibits a more or less pronounced laceration, with ectropium, erosion, ovula Nabothii, and general hyperplasia of its tissue, and the assured determination of minute cancerous nodules beneath the mucous membrane or of a beginning malignant change in an erosion is a matter requiring the greatest possible degree of tactile skill and familiarity with the diseased conditions in this locality. The presence of small, hard nodules over which, possibly, the mucous membrane is immobile, in parts of the vaginal portion where there is no cicatricial plug, may point to the existence of one form of beginning cancer. It goes without saying that, since the microscope often fails to distinguish between a benign papillary erosion and one in which malignancy has already developed, the differentiation of these conditions by unaided sight or by touch is a matter of the most extreme difficulty. Such areas probably bleed more readily when the seat of beginning carcinoma, but this is purely a relative sign and without much value.

Stratz points out that the diseased portion is sharply separated from that which is healthy ; there is a difference in level between the diseased and healthy areas ; the former is at a lower level and has a hard surrounding border, and the malignant surface has always a faint yellowish color and is covered with finely granular whitish-yellow elevations, at least in some places. The same author, however, observes that clinical observation alone, far from determining the diagnosis of commencing carcinoma, can only raise suspicions which the microscope is called upon to settle. But from the fact that the material sent to the microscopist is often inadequate, and because of the close similarity in minute structure between the benign papillary erosion and the malignant papilloma, even the microscope often fails, as in the cases cited by Landau, to settle the matter finally. If the portion of doubtful tissue submitted to the microscopist is sufficiently large to permit of many sections being prepared from it, is removed from the most suspicious portion of the cervix, and is made to include not only the mucous membrane but a considerable portion of the underlying muscular tissue, his opinion will be immeasurably enhanced in value.

It behooves the examiner, being assured that there is malignant disease present, to ascertain with the greatest possible accuracy its extent ; for only in this way can an operation be selected which is at all likely to be followed by radical results.

The diagnosis of cancer in its advanced stages is easy and requires no comment.

THE MUTUAL RELATIONS BETWEEN CANCER OF THE CERVIX AND CHILDBEARING.—I must confess that I can see no reason for the statement, so often repeated, that pregnancy occurs very readily in the early stages of cancer of the cervix. The fact that patients with this disease have usually reached the limit of childbearing life, and from repeated pregnancies have already pretty well exhausted their procreative powers, militates decidedly against any such assumption. Furthermore, it is in just such women that one would expect to find the results of parturient injuries of the cervix. These are universally regarded as causes of sterility ; and since some forms of beginning epithelioma are simply pathological exaggerations of the changes which follow lacerations, and others, to all intents and purposes, are undistinguishable therefrom, it seems irrational to assume *a priori* that incipient cancer favors conception. Nor, aside from pre-existing lacerations, ectropium, and erosions, is there anything in the commencing malignant changes in a previously uninjured cervix that would seem to make pregnancy anything but difficult. In fact, in spite of Cohnstein's statement that in 127 pregnant women with cancer of the cervix there were 21 in whom the disease had been recognized for a considerable time before the occurrence of pregnancy, it is admitted on all sides that the complication of childbearing with this affection of the cervix is extremely rare. Thus, according to Stratz, in 1,034 cancer patients observed in the last ten years in the Woman's Clinic of the Royal University in Berlin, conception occurred in but 1.16 per cent., and in 17,832 deliveries which took place during the same time only 0.039 per cent. were complicated by this disease.

Conception may occur even in women with far advanced carcinoma of the uterine neck, but such a circumstance is extremely uncommon.

It is generally agreed that during utero-gestation the malignant affection, as would naturally be supposed, makes extremely rapid strides ; and yet many have observed instances in which there seemed to be no progress, or in which the disease advanced with great slowness.

Provided pregnancy occur in a woman with cancer of the neck of the uterus, there is developed one of the most frightful complications which the physician can be called upon to meet. In such cases, according to Lewes, forty per cent., to Cohnstein, fourteen per cent., and to Stratz, from thirty to forty per cent. abort or suffer premature delivery. Occasionally, however, pregnancy goes to full term, and, rarely, is still further prolonged, owing, as Pfannkuch suggests, to the fact that the density of the lower uterine segment is sufficiently great to overcome the efficacy of uterine contractions, and because the destruction of important nerve-endings at the seat of the disease may prevent the reflex stimulation necessary to bring on labor.

When delivery occurs it becomes prolonged, difficult, or dangerous in proportion to the amount of resistance offered by the infiltrated cervix and lower portion of the corpus uteri. Expulsion of the child may be, indeed, impossible, or is accomplished only at the cost of wide-spread laceration and crushing of tissue.

The mortality to both mothers and children, in the event of the coexistence of utero-gestation and advanced cancer of the neck of the uterus, is enormous. Chantreuil reports that of 60 cases 25 mothers died during, or immediately after, labor, and 29 children were born dead. Herman mentions that in 180 confinements 72 mothers died, and of 114 children of whom record was made but 58 were born alive. According to Cohnstein's investigations spontaneous labor terminated favorably for the mother in 37.5 per cent., and for the child in 33.3

per cent. of the cases; but when the disease was advanced only 34.7 per cent. of the mothers recovered and but twenty-five per cent. of the children were born alive.

The treatment of a pregnant woman suffering from cancer of the neck of the uterus requires much consideration. When it is remembered that the vast majority of such individuals die either directly from the effects of labor, or, should they survive, are probably beyond the reach of material help, the life of the child becomes a matter of the greatest importance. Surgical interference during pregnancy is very apt to be incomplete, and there is added the risk of abortion or premature delivery. At term the accoucheur may expedite labor by securing enlargement of the cervical canal by dilatation or incision, and by rapid manual or instrumental extraction of the child, or through craniotomy if the child be dead.

When the disease during utero-gestation is so far advanced as to threaten the life of both mother and child, it may be well to have resort to some palliative operation in order, if possible, to keep the patient alive until the child is viable and then induce premature labor. In instances where the disease apparently is not extensive, in the interest of the mother it might be well to sacrifice the child, inducing abortion, and then performing total extirpation of the uterus.

Cæsarean section may be undertaken near the normal end of pregnancy in cases where delivery, per vias naturales, appears to be impossible, or hedged about with difficulties and dangers. This is certainly the most assured way of preserving the life of the child, and should be attended with less risk for the mother than when labor is allowed to take place in the usual manner.

According to Herman, up to 1879 the maternal mortality of Cæsarean section under these conditions was 72.7 per cent., and in 12 cases collected by him, 10 children were removed living from the uterus.

Among 135 Cæsarean sections done according to Sänger's method, between May 25, 1882, and October 1, 1888, and recorded by Sänger (Nos. 1-10), Credé (11-50), and Caruso (51-135 inclusive), in four instances the operation was performed upon women suffering from cancer originating in the cervix uteri. All the children and two mothers were saved. The operators were Jewett, of Brooklyn; Ehlers, of Braunschweig; Lusk, of New York; and Merkel, of Nürnberg. Frank, of Cologne, and Goodell, of Philadelphia, have very recently performed Cæsarean section for the same indication. In the case of the former, a twin pregnancy, one child was already dead and partly macerated, but the other child and the mother were rescued. In Goodell's case both mother and infant were doing well on the thirteenth day, the date of the report. Frank's operation was performed according to a method of his own, and was reported by Beaucamp.

TREATMENT.—Such general treatment as is necessitated during the various stages of carcinomatous disease of the cervix uteri need be here described in no detail. Until the effects of infiltration are felt in pain, and of destruction in hæmorrhage and exhausting discharge, the physician's counsel is usually not sought. The management of the patient during the later periods and closing scenes of the affection taxes all the resources at our command. Gradually one system is involved after another, and life finally becomes simply an exhibition of variously diversified combinations of morbid phenomena.

Really, all general treatment expresses only the effort made to prolong existence, or to make it more bearable, and at last with narcotics to cheat death of its horrors.

The effect to be exercised in the future upon the whole matter under discussion in these pages, by the establishment and careful and intelligent conduct of hospitals especially designed for the treatment of cancer, cannot be at present estimated. Not only will they become a refuge where these miserable sufferers who have abandoned hope may find some mitigation of their wretchedness, but also sources of instruction in everything which pertains to this dreadful disease for their corps of medical attendants, both old and young, and through them for the whole profession. The mortality of ovariotomy has been immensely lessened by the early recognition of ovarian tumors and the improved technique employed in their removal. Ectopic pregnancy is no longer a condition of whose early history we know nothing and for which we can do nothing. And cancer of the cervix, which in its incipiency is as much a localized affection as any other, may, largely through the influence of the institutions of which I here speak, cease to be a synonym of all that is most horrible in a woman's life.

It is impossible, in discussing the treatment of carcinomatous disease of the cervix uteri, to institute any formal divisions or subdivisions, or to speak with any degree of accuracy of symptomatic, palliative, or radical therapeusis. The treatment of the vast majority of symptoms is practically the treatment of the disease. A so-called palliative procedure may be unexpectedly followed by the complete extinguishment of the affection, and the most radical of all operations—total extirpation—not only proves in a large number of cases to be an utter failure as far as complete cure is concerned, but, on the other hand, has been performed where the disease was known to have passed beyond limits that technically could not be overstepped by the surgeon; where, therefore, the operation becomes a palliative and not a radical procedure at all.

Almost any operative method or device which is directed against the disease in situ may be either palliative or radical. Even the simplest may be completely effective when the disease is limited to the anatomically isolated cervix; but when it has insinuated itself through or swept aside anatomical boundaries the most thorough may prove a dismal failure.

Unfortunately, we have no means of knowing what ground cancer has already occupied by its outposts. Areas of thickening and resistance along possible avenues of travel may indicate where the disease is already present in force; but who can follow the smaller bodies of the enemy as they scatter far and wide, invading only to devastate?

With regard to prophylaxis, it need only be said that since cancer of the neck of the uterus is most common in women who have had many children; since a very large proportion of these have either suffered a visible laceration of the cervix, or else some less pronounced parturient injury; because we know what are the almost inevitable pathological accompaniments and sequelæ of such injuries; and because it is certain that the transition between the most common of these accompaniments and sequelæ and cancer has been clearly demonstrated, and is so slight a change as to leave the most careful examiner often in doubt as to whether the existent condition is benign or malignant; admitting these statements to be facts, the only logical deduction to be drawn from them is that a laceration or other injury of the cervix uteri must be regarded as an important pathological entity, and quite independently of any subjective symptoms that may or may not be present at the time, and, therefore, must be repaired early and repaired thoroughly. Any other disease involving the various tissue-elements making up the neck of the uterus should no less receive attention.

In the succeeding lines some of the methods of treatment employed with the object of mitigating or thoroughly eradicating the disease in question will be discussed, and the arrangement followed will imperfectly indicate the various steps in the history of the treatment of cancer of the cervix.

The removal or destruction of cauliflower excrescences projecting into the vagina, of cancerous ulcers, or of sloughing masses, and the infiltrated tissue in their immediate neighborhood, by spoons, curettes, caustics, etc., at one time regarded as an effective method of treatment, is now employed practically only in so-called inoperable cases, and the object aimed at is not cure, but relief and prolongation of life through prevention of hæmorrhage, gangrene, and foul discharge.

With a curette, sharp spoon, or scoop, assisted by knife or scissors, as much of the disorganized tissue is removed as possible, and while it is desirable to do this thoroughly and to go deeply, care must be exercised not to wound either the bladder, rectum, or peritoneum.

After this removal has been satisfactorily accomplished, selection may be made from a large variety of methods of subsequent treatment. The wound may be at once cauterized with heated irons or with the Paquelin instrument, and this also should be done in no superficial or perfunctory manner. The excavation produced can be kept clean by iodoform powder and an iodoform-gauze vaginal tampon ; or a pledget of some absorbent material saturated with alcohol may be introduced instead. A large number of cauterizing agents have been employed, alone or in diverse combinations with other procedures ; among them, bromine, nitric acid, carbolic acid, Vienna paste, caustic potash, the positive pole of the galvanic current, and chloride of zinc ; the last, perhaps, the most extensively. Sims, as is well known, in 1879 extolled the virtues of chloride of zinc ; Van de Warker, in 1884, again brought it to the attention of the profession ; and more recently still (1888) Fränkel, of Breslau, has proven its utility when preceded by the use of the spoon and the Paquelin cautery. In 50 cases of so-called inoperable carcinoma of the cervix in Fränkel's hands, there were 6 in which the disease was thus radically cured. After the spoon and actual cautery have been employed, iodoform is sprinkled over the wound, and an iodoform-tannin-gauze tampon is placed in the vagina. When the separation of the charred tissue occurs, provided no suspicious points are visible, Fränkel advises that a small pledget of some absorbent material, soaked in a 2-to-3 solution of chloride of zinc, be placed in the excavation, while the vagina is protected by an ointment or tampon containing bicarbonate of soda. The cotton soaked in zinc is removed in from twelve to twenty-four hours, and a thick, grayish-white scab is apparent, which becomes detached in from eight to ten days, leaving a surface covered with healthy granulations. With the aid of disinfecting vaginal injections and loosely placed iodoform-gauze tampons, the wound rapidly cicatrizes.

As Fränkel suggests, these various steps should be modified from time to time to suit the exigencies of individual cases ; the strength of the chloride of zinc solution should not be invariable, but should depend upon the depth of cauterization which it is desired to achieve, and the length of time that the tissues are to be exposed to its action. He believes, finally, that recurrence *in loco* is more uncommon or longer postponed after the use of chloride of zinc than when other drugs of a like character have been employed.

Still, as Ehlers and others have pointed out, the idea that chloride of zinc exerts any specific action upon cancer is untenable, and while its use is admirably adapted to certain cases of advanced carcinomatous disease, yet it is not always possible to limit its action to the affected area, and sound tissues may be attacked even when it is carefully employed.

I should like at this point to refer to a rather unique method advocated by J. Schramm, of Dresden, in the treatment of inoperable carcinoma of the cervix. This author especially recommends the injection of antiseptic fluids directly into the cancerous tissues. He believes that, even if the existence of a micro-organism as the causative factor in cancerous disease has not as yet been firmly established, yet sufficient has been proved to make a procedure like the foregoing a rational one. He employs a solution of corrosive sublimate. A needle of a hypodermic syringe is carefully introduced into the carcinomatous mass until slight resistance is encountered, and the fluid is then gently evacuated drop by drop. This injection is repeated, sometimes deeply, sometimes superficially, two or three times a week. No fear of sublimate intoxication need be entertained (although 0.008 to 0.010 gramme of the antiseptic is employed at each sitting), for the absorptive power of the degenerated tissue is almost nil. The malignant mass, it is claimed, is kept clean by this treatment, the purulent discharge ceases, further destructive change is diminished, hæmorrhages become less frequent, and the general condition of the patient improves.

Repeated and prolonged vaginal irrigation with very hot water, specially commended by Tornery, or the use of disinfectant and deodorant solutions, particularly those containing permanganate of potassium, or a two per cent. solution of creolin (as suggested by Coe), are of great service in combating the ichorous discharge and the foul odor which surrounds the patient like a noisome exhalation. Iodoform powder and loose iodoform-gauze tampons, likewise, employed in the intervals between the injections, are of the greatest utility.

Terebene, Chian turpentine, and Alveloz, have their place in the treatment of the advanced stages of cervical carcinoma. Each has its special advocate, but it is probable that we could get along very well without them.

With the view of thoroughly eradicating the carcinomatous disease when it is confined to the cervix uteri, numerous operative procedures have been proposed and practised. The object sought in all of them is, not only the removal of such tissue as shows palpable signs of degeneration, but also of that beyond which is, or is likely to be, infiltrated ; the operation being continued, therefore, well into areas which, so far as can be ascertained, are free from the slightest suspicion of malignant invasion.

When the portio vaginalis alone, the cervix alone, or both together are the seat of cancer, and there is reason to suppose that there has been no further extension, the amputation, or better, excision, of a part or the whole of the neck of the womb should offer fair chances of immediate and permanent success. Even the most thorough operation of this kind presents few difficulties and is attended with a low rate of mortality ; and further, the ultimate results are quite satisfactory, as will be shown immediately.

The portio vaginalis may be amputated by the écraseur, galvano-cautery, or knife and scissors. Even the most improved écraseurs are difficult to use, are liable to do injury, and possess no special advantages. The cautery wire is not always easy to apply, but diminishes the chances of hæmorrhage during and after the operation. The fact that it cauterizes the tissues left behind is at once an advantage and a disadvantage. For, while this charring of the stump may in one sense be regarded as advantageous, it nevertheless may prevent the appreciation of the fact that the operation has not been thorough, and that distinctly infiltrated spots remain in the wound.

The ablation of the vaginal portion with scissors is to be preferred to either of the methods of procedure just described. To those who are accustomed to the performance of plastic operations upon the cervix, it offers no difficulties whatsoever. To be thorough, the cervix should be split into an anterior and posterior half, and each lip exsected beyond the limits of the portio vaginalis proper, so that a triangular wound is left whose base is formed by the vaginal roof, and whose apex reaches to or beyond the internal os uteri. Thus, while some of the tissue of the cervix remains, the mucous lining and submucous strata of the canal are removed,—a point of considerable importance when it is remembered that these areas are early affected by the gradual upward extension of the disease when it originates below, and may themselves be the seat of a coincident malignant process. It is better, it would seem, to pursue this plan of operation than to have recourse to any of the more formal methods whereby a portion of the mucous membrane of the cervical canal is preserved. Deep silver sutures, or the actual cautery, if it is not desired to approximate the edges of the wound, will control any hæmorrhage that may ensue, and a hollow glass stem pessary or roll of iodoform gauze will prevent the complete closure of the cervical canal. We should here be dominated by the thought that we are operating for a disease whose limits of extension are not ascertainable by any means in our possession, and should, for the sake of thoroughness, forego the satisfaction that one necessarily feels in doing a neat plastic operation.

As has been already mentioned, the immediate and remote results of the various operative methods of ablation or excision of the vaginal portion, with or without cerable parts of the cervix—in brief, of all removals of the neck of the uterus short of supra-vaginal amputation—have been very satisfactory. Gusserow has assured himself that radical cure was obtained by Simpson, Marschik, Zeemann, C. Mayer, Martin, Grünewaldt, Schultz, Hegar, and Sebastian. C. Braun has operated 166 cases, with the following results: 10 deaths, and 16 patients received no benefit. Of 140 immediate recoveries, 52 subsequently died, but only 16 of actual recurrence; 22 patients were lost sight of; 33 remained well for from one to eleven and a half years. Schroeder reported 13 cases, of which number 1 died of trismus. Of the remaining 12, 4 suffered a recurrence within two years, and 8 continued well at that date. Byrne, of Brooklyn, has used the galvano-caustic wire in 300 cases, and has never seen recurrence at all.

Schroeder's supra-vaginal amputation of the cervix, the next operation to be described, is indicated when the carcinomatous disease has begun in the cervix, or in the more advanced forms of certain varieties of cancer of the vaginal portion; but in either case, for the operation to be permanently effective, there must be no extension beyond the neck of the uterus.

It should be said at once, however, that no specific indications for any of the preceding or succeeding operative procedures can be formulated; that no inflexible rules for the guidance of the gynecologist can be laid down. Each operator must judge of each case upon its own merits; and while statistics may give a fair idea of the immediate and remote results which pertain to any individual method, it is a question whether anything can be learned from their comparative study. With the passage of time, the constant tendency has been toward the adoption of more and more radical measures, even in cases where those which were less bold and thorough were formerly thought to be satisfactory enough. This tendency may be accounted for by the increased confidence which gynecologists have begun to feel in their operative skill, and also by the fact that the frequency of recurrence after less pronounced surgical interference has excited everyone who has the welfare of his profession at heart, to seek out some new method which theoretically should be followed by greater immunity from return, and whose utility can be practically tested. We are not in a position to-day to decide between the merits of many of these operations. It is a very easy thing for a writer to describe what has been done, but it is another matter when it comes to be said what should be done. Ovariotomy may be a closed book, but cancer of the cervix is practically one which is just being opened, and he who will come nearest to the solution of the riddles contained therein must have, aside from any personal qualifications, a large material at his command, and the possibility to follow up his cases.

In the supra-vaginal amputation the cervix is first brought down and separated from its vaginal attachments by knife or scissors. The connective tissue in which the cervix proper is embedded is next stripped off with the finger, the bladder likewise is freed, and ascends, carrying the ureters with it beyond the risk of injury. When the summit of the cervix is reached, first one half and then the other is cut away, and the anterior and posterior portions of the stump are stitched to the vaginal mucous membrane, respectively at the front and back of the incision made through it. It is a matter of choice whether the incision through the vaginal fornix is first made in front, behind, or at the sides of the cervix; and of indifference whether the pouch of Douglas is opened or not, provided, of course—it is almost unnecessary to say—that the operation is conducted with the utmost regard to surgical cleanliness.

One or two features of the operation, however, require special comment. Hæmorrhage may originate from the divided surface of the vaginal wall, and it is sometimes necessary, when this has been attacked by cancerous ulceration, to resect considerable portions of it, in which case small clamp-forceps or a suture passed parallel to the incised surface and around the bleeding vessel will usually be sufficient. But troublesome bleeding is far more liable to result from the vessels which enter at the sides of the cervix, where also the connective tissue is most dense. This may be controlled by forci-pressure, or by one or more ligatures previously introduced on a curved needle carried high through each lateral vaginal fornix, as in the first steps of vaginal hysterectomy. It is best, also, after separating, let us say, of the anterior wall of the cervix, to sew the stump to the corresponding portion of the wound in the vagina, for hæmorrhage thereby is controlled, and by traction upon the long ends of the ligatured suture the cervix is prevented, when the posterior wall is divided, from escaping beyond our reach.

There are numerous other technicalities and modifications of Schroeder's supra-vaginal amputation of the cervix about which it is unnecessary to describe. Hofmeier has recently given in complete detail the method pursued in Schroeder's clinic during the closing years of the latter's life.

Statistical evidence bearing upon the safety and ultimate effectiveness of this operation, as well as of Baker's, Freund's, and of vaginal hysterectomy, will be cited at the close of this article.

In our advance from the simplest to the most radical methods employed in the treatment of carcinoma of the neck of the uterus, allusion must next be made to that described by Baker, of Boston, in 1882 and again in 1886. In this operation the cervix is freed from its attachments and removed as in the supra-vaginal amputation. Then with a uterotome a funnel-shaped excavation is produced, whose base is on a line with the internal os, and whose apex approaches or meets the fundus of the uterus. "It is thus possible to remove the entire cervix, both infra- and supra-vaginal, and at the same time nearly or quite one-half of the body of the uterus, and that the most important half; for cancer of the body of the uterus, whether of primary origin or of extension from the cervix, affects the glandular structure first, and by the method I have described, this, its natural habitat, is removed or destroyed" (Baker). The edges of the vaginal wound, provided not too much has been removed, as may have been made necessary by the extension of the disease in that direction, should next be stitched to what remains of the lower part of the uterine wall, and the actual cautery is then applied to the whole denuded surface. In this operation the diseased portions of the vaginal walls, and, with some slight modifications, the para-cervical connective tissue, along with the whole of the neck and a considerable portion of the body of the uterus are removed. Practically nothing remains but a rounded shell of healthy muscular tissue with a thoroughly charred cone-shaped interior. Baker's results have been most gratifying, as will be seen later on.

In 1878 Freund, of Strasburg, introduced an operation that has subsequently borne his name, which consists essentially in the removing of the entire uterus by abdominal section, the broad ligament of each side being tied off in three portions before being divided, and the separation of the vagino-uterine attachments being accomplished by dissection made from within outward.

Even in the hands of the most skilful and experienced German operators—for in Germany its practicability was most often tested—Freund's operation has been attended with such disastrous results that, even though it afforded an absolute guarantee against the recurrence of cancer, which is very far from being the case, it could in its original form be no longer classed in the category of legitimate operations.

Long before this time, namely, in 1822, Sauter, of Constance, had performed total extirpation of the uterus per vaginam, and the operation was repeated by Blundell, in 1828, and Recamier in 1829. After being forgotten or neglected for many years, it was revived by Czerny, of Heidelberg, in 1878, and was soon thereafter taken up by Billroth, Schroeder, and others in Germany, and by operators generally throughout the world. It will be impossible to bestow more than a glance upon this operation of vaginal hysterectomy, or total extirpation, upon the indications for its performance, its imitations, technique, difficulties, and dangers; for since its introduction, ten years ago, such an amount of attention has been given it that the mere enumeration of the literature that has accumulated during this period would be a limitless, if not an impossible, task.

Vaginal hysterectomy is a surgical procedure which is at once radical and comparatively safe. At the present time there is no means in our possession of so thoroughly eradicating cancerous disease of the uterus. It is applicable in all the cases in which supra-vaginal amputation is performed, and can be resorted to when this latter operation would be merely a palliative and temporary expedient. The tendency of the time is toward the adoption of vaginal hysterectomy, to the exclusion of all other operative means of combating cancer of the cervix. That, of course, each has its indications and limitations goes without saying. But since no one can know before removal of the uterus how extensively its lining membrane is affected by secondary, incipient, malignant degeneration; nor whether isolated and coincident carcinomatous disease exists therein; and because recurrence *in loco* has so frequently been observed after less radical methods of removal where everything gave the most assured promises for the future; even the most experienced and conservative gynecologists of late have entertained and expressed a preference for total extirpation as against less thorough modes of operative interference. As Brennecke has pointed out, if the uterus is removed the patient will be spared the risks of a subsequent pregnancy, and Landau maintains that the uterus to a woman past the childbearing age is of no use whatever. Furthermore, Brennecke observes that extirpation of the uterus puts an end to the free monthly bleeding due to coexisting endometritis; but it might be urged that Baker's operation, thoroughly done, would be quite as effective.

A great deal might be said upon the opposite side of this question, and there are doubtless not only many instances where the removal of the uterine neck would have been quite adequate to annihilate the malignant disease, but also where the uterus has been extirpated for supposed cancerous, but really perfectly benign, conditions. Reeves Jackson is a bitter opponent of total extirpation. He maintains that "Kolpo-hysterectomy is more dangerous and has given worse results than any other method of treatment. It has destroyed and not saved life. It is an injurious and not a successful operation. It is more rapidly destructive of life than the disease against which it has been used. Hence it should be condemned as unjustifiable."

Whether vaginal hysterectomy is an operation which warrants all the trust imposed in it by some, or deserves all the opprobrium cast upon it by others, time alone can show.

The absolute restriction of the cancerous affection to the uterus is the most favorable condition for the immediate and remote success of vaginal hysterectomy. It was, and still is, generally believed, that unless there is sufficient evidence to warrant the assumption of such limitation, total extirpation is contra-indicated. It certainly, in this sense, cannot be regarded as a radical operation. But we are unable to affirm that the disease is confined to the uterus, although the extreme mobility of that organ and the freedom from induration in its surroundings, doubtless point in that direction. Still, on the one hand, the extension of cancer is not always appreciable by the senses of which we make use in examining women, and on the other, quite distinct areas of thickening may be due to the remains of a previous para- or peri-metritis antedating and unconnected with the malignant disease of the cervix.

Vaginal hysterectomy is, however, no longer confined within the narrow boundaries which formerly hedged it in. In certain quarters these boundaries are being extended, and in cases where no hope of radical cure can longer be entertained, total extirpation is recommended as the best of all palliative methods of treatment. Many of those whose names are identified with the history and progress of the operation under discussion—among them, Richelot, B. Schultze, and Brennecke—would extend the limits of the operation to the utmost bounds of technical possibility. It is argued that no other palliative procedure secures to the patient such marked and prolonged relief. Thiem is an ardent advocate of this aspect of the question, and points out that if recurrence takes place after vaginal extirpation, it is not as an ulceration, but as a tumor formation in the scar. The woman, therefore, may die of cancer of other organs or of cachexia, but is spared the horrible gangrenous degeneration in the vagina which of all things makes carcinoma of the cervix such a loathsome affection. With due regard to the universal applicability of Fritsch's axiom—"aussichtslose Operationen zu machen ist ein inhumaner Sport,"—Thiem believes that total extirpation in every case offers the best chances to the patient, and that all so-called inoperable cases are really operable so long as the operation is within the bounds of technical possibility.

It would be impossible to describe all the modifications of technique that have been introduced in vaginal hysterectomy. Most of them, as Martin shows, are really matters of no great importance, as is proven by the almost uniform results obtained by different operators using different methods. There are a few which have exercised a considerable influence upon the history of the operation, and to these reference will be made.

The patient is prepared in much the same way as for any important surgical procedure; the condition of the gastro-intestinal canal, skin, and kidneys receiving special attention. A few days before or immediately preceding the operation, the degenerating cancerous mass which presents in the vagina should be removed, and, indeed, it may be expedient to excise the entire cervix. The hair should be shaved from the external genitals, which are then cleansed thoroughly with soap and water, and afterward with some antiseptic solution. Every effort should be made to render the vagina completely aseptic, and to this end repeated irrigation with a 1 to 1,000 or 1 to 2,000 sublimate solution should be practised; or, bearing in mind the experiments of Döderlein and Günther in the disinfection of the parturient canal, the mucous membrane must be thoroughly scoured, if I may use the term, with a sublimate or creolin lotion. The operator, his assistants, and attendants, should be no less careful about themselves and the instruments, etc., employed.

The time for the operation having arrived, the patient, lying on her back, is brought well to the edge of the table, and with the aid of anterior, posterior, or lateral retractors, and sometimes all are necessary, the vaginal portion and vaginal roof are exposed. The portio vaginalis is seized with a vulsellum forceps and drawn downward; or, if this has been previously removed or the forceps does not hold, a stout ligature may be passed through what remains of the cervix, or the uterotractor of Bernays, or endoceps of Richelot or of Brennecke may be introduced directly into the uterine cavity. The cervix is then to be freed from its anterior and posterior vaginal attachments and from its surrounding cellular atmosphere, and the connections of the posterior bladder wall are to be liberated in the manner described when speaking of supra-vaginal amputation. It is a matter of indifference whether we begin the operation in front or behind the cervix; but the plan of attacking the lateral vaginal fornices first (Polk, Fritsch) commends itself from the fact that not only is subsequent hæmorrhage thereby diminished, but the uterus at once attains an increased degree of mobility, and can be easily moved in different directions by the forceps or ligature attached to it. Constant irrigation of the field of operation can be practised up to this point, and now it is well for the operator to cleanse his hands and to employ fresh instruments and sponges, provided the latter have been used before.

Either the anterior or posterior peritoneal pouch may be first opened, the peritoneum being seized with a forceps, a button-hole made in it with scissors or knife, and the membrane then cut or torn in each lateral direction.

The most important part of the whole operation of vaginal hysterectomy is the securing of the broad ligaments in such manner as best to prevent hæmorrhage from the divided edges when the uterus is cut away. Practically, all the important vessels encountered by the operator run beneath the peritoneal duplicature constituting the framework of these ligaments. Formerly the ligament of each side was tied en masse, the fundus often being turned over and brought through the opening in the anterior or posterior cul-de-sac to facilitate this manœuvre. Various modifications and combinations of different methods of procedure have been introduced from time to time, the object of all being to give the utmost security against hæmorrhage. The demonstration by Richelot of the applicability of certain forms of long, stable forceps was an important step in advance. It has been shown not only that forceps can be trusted quite as much as the ligature, but that they can be adjusted more easily, more rapidly, and further, can be employed in certain cases where the use of a ligature would be impossible. The utility of the forceps has been advocated by Richelot, of Paris; Landau, of Berlin; Müller, of Berne; Hunter and Polk, of New York; and Dudley, of Chicago.

When the ligature is used, as is almost universally the case in Germany, a curved needle armed with stout silk is introduced through the lower portion of the broad ligament of one side, the ligature is tied, and the ends left long. The tissues lying between the ligature and uterus are then divided. This process is repeated, constantly going upward, until, finally, the summit of the broad ligament, with the Fallopian tube, ovarian artery, and pampiniform plexus is included in the last ligature and, after this is tied, the attachments of the uterus on that side are entirely severed. The other side is treated in the same way, a very much easier matter, and finally the uterus is completely freed and delivered. Certain operators tilt the fundus uteri through an opening previously made in the anterior or posterior cul-de-sac to render easy of access the summits of the ligamenta lata, but others satisfy themselves with traction on the uterus in situ.

When the forceps is used, it is best, as Richelot suggests, first to make an opening anteriorly and posteriorly in the peritoneum. The index-finger of the left hand introduced through the latter acts as a guide along which one blade of a long forceps, such as those devised by Doléris or Polk, is inserted. The other blade is passed through the anterior opening, and the finger hooked over the top of the broad ligament draws it down within the grasp of the blades, which are then clamped, and the tissues lying between the forceps and the uterus are divided. Again, especially when this manœuvre is difficult or impossible, forceps with shorter blades are used, and the broad ligament is seized and divided in tiers, as described by Hunter (of New York), the pincement par étages of Richelot. The number of pairs of forceps requisite to control all hæmorrhage is sometimes enormous. They are removed usually in from twenty-four to seventy-two hours.

Hæmorrhage may originate from sources other than those already described, but can usually be controlled by small compression forceps, or, if from the divided vaginal wall, by transfixing and tying around the vessel.

Occasionally during the course of the operation the bladder is wounded, or along with a necessary resection of a part of the vaginal wall it may become advisable to remove a part of the bladder. In either case the fistula should be at once closed.

Great care must be exercised to avoid injuring the ureters with cutting instruments when operating in front of the cervix, and to prevent including them in the ligature or grasp of the forceps. Such unfortunate accidents have occasionally occurred (Richelot, Kocher, Lannelongue, Doumer). After having divided the anterior vaginal wall the finger alone should be employed to free the supra-vaginal cervix, and when this separation is carried to a sufficient degree in a lateral direction, there will be slight risk of catching the ureters when employing either of the hæmostatic measures just alluded to.

After the uterus is removed there remains a large funnel-shaped cavity. A considerable diversity of opinion exists, or rather existed, as to the treatment of this wound, for now it is generally considered quite judicious to leave it alone. With the idea of preventing intestinal prolapse and infection from without, but at the same time of securing adequate drainage, a host of procedures have at various times been inaugurated. Bouilly recounts no less than thirteen. At the present time, however, a large number of operators discard all suturing and artificial methods of drainage, contenting themselves with placing in the vagina a loosely made tampon of iodoform or creolin gauze. The wound under favorable circumstances heals rapidly and firmly. The patient, as a rule, behaves after vaginal hysterectomy more like a puerpera than a woman who has undergone a serious operation. The ligatures or forceps are removed as already indicated, and the dressings changed at or near the end of a week. Then, after gently practised vaginal irrigation, some fresh iodoform gauze is loosely inserted into the vagina. The urine is drawn by catheter for two or three days, and a movement from the bowels is secured on the fifth to the seventh day. In the second or third week the patient may be allowed to sit up.

Lusk observes that "the safety of the woman after extirpation of the uterus depends upon strict antisepsis and the careful control of hæmorrhage at the time of operation," and it is unquestionably true that death after vaginal hysterectomy is usually due to lack of these precautions. Nevertheless, ileus may develop after the operation, in a manner described in detail by Reichel, and at least five deaths have been due directly to this cause, or have followed laparotomy undertaken for its relief. These fatal cases have been reported by Bokelman (death from intestinal obstruction on the seventh day after total extirpation of the uterus), Leopold (death on the fourth day), Landau (abdominal section for intestinal occlusion, the case terminating fatally on the day next succeeding), and Reichel (death during laparotomy on the seventh day, and a second case, where the patient succumbed twenty hours after abdominal section on the ninth day after operation). A. P. Dudley has recorded a case in which the bowel became obstructed one and a half years after the vaginal operation, but an entero-vaginal fistula formed and the patient recovered.

Sometimes during the operation of total extirpation of the uterus the ovaries and tubes prolapse and may easily be removed. It is best, it may be said, to remove them in every woman who has not reached the climacteric, and wherever else it can be done without unduly prolonging the operation; for it adds nothing to the danger, and undoubtedly materially enhances the future comfort of the patient. The ovaries without the uterus can serve no good purpose whatever. Even Brennecke, who maintains that their removal is attended by no special advantage, admits that in all of his patients where this was not done there was marked pain of different kinds for one or more days, at regular intervals, for the first two to six months after the operation, accompanied by epistaxis, flushing, headache, and other disturbances of a distinctly molimenal character. His opinion is that the ovaries soon cease performing their usual functions and atrophy, but Grammatikati, who to ascertain what really became of the ovaries after total extirpation of the uterus performed experiments upon numerous rabbits, comes to a different conclusion. The latter insists that the ovaries continue to functionate, and that no change can be discovered in the ripening or rupture of the Graafian follicles or in the structure of the false corpora lutea. The specimens removed from a patient, dead of an intercurrent disease three years after vaginal hysterectomy, strongly supported this view.

Here are certainly a sufficient number of operative procedures to be employed in the various stages of cancer of the uterine neck to suit the most exacting, and Schroeder's modification of Freund's operation, Rydygier's combination of Freund's operation and vaginal hysterectomy, and numberless other methods of surgical interference, should still be mentioned. But it is in very few instances of the disease that anything beyond mere palliation can be secured. The proportion of cases that have passed beyond all hope of permanent relief is simply enormous. The number of those which are unsuitable for even the most radical of the palliative methods is great. Leopold, in 250 cases, found that but 42 could be designated operable, and the experience of Thiem, Schatz, Cordes, of Geneva, and in fact of every gynecologist, is almost precisely the same.

The choice of operation in a given case, as is self-evident, depends upon many considerations. A number of these determining factors are apparent at a glance, while others depend upon the individuality of the operator. As Lusk observes, complete cure can only be secured by removal of every particle of diseased tissue; but whether this can best be done in one way or another is a matter which cannot as yet be considered fully determined.

It may be well, therefore, while admitting that statistics are not always conclusive, to append an outline of the results obtained through the employment of some of the operations just described, in the hands of a few well-known and conscientious gynecologists.

1. *Supra-vaginal Amputation of the Cervix.*—Schroeder's statistics, as recorded by Gusserow, 1886: Number of cases, 105; deaths from operation, 13; recoveries, 92; lost sight of, 27. Twenty-seven showed recurrence within six months; 38 remaining well at this time. Twenty-seven well after one year; 22 after eighteen months; 18 after two years; 15 after two and a half years; 12 after three years; 5 after four years. The remaining cases were lost sight of, or experienced a recurrence.

Martin, 1887, says that the operation mortality, according to Hofmeir, is 7.4 per cent., and that fifty-five per cent. of surviving patients remained well at the end of the first, and thirty-three per cent. at the end of the fourth year. His own immediate mortality was twenty-one per cent., and every survivor was the subject of recurrence.

2. *Baker's Operation.*—Reeves Jackson, 1887, reports 21 operations, with an immediate mortality of 9.5 per cent. Of those who survived, 9 remained well, one after three years and eleven months, another three years and seven months, another two years and two months, another one year and eleven months, another one year and nine months, another nine months, another six months, another five months, and another after four months. In 6 cases there was recurrence and subsequent death. Four patients passed from under observation.

Baker, 1886, records 10 cases with no deaths due to the operation. In 3 there was recurrence *in loco*, and another died of cancer of internal organs. Six of the patients continued well for from four to eight years after the operation.

3. *Freund's Operation.*—Gusserow, 1886, records 148 operations with 106 deaths, a mortality of 71.6 per cent. The disease recurred in every reported case, and ultimately death ensued. Fritsch, 1887, mentions that one patient, operated upon by Freund eight years before, yet lives and is in good health.

4. *Vaginal Hysterectomy* or *Total Extirpation.*—Gusserow, 1886, records 253 operations with 59 deaths following, a mortality of 23.3 per cent.

Pfannenstiel, 1885, quoted by Gusserow to show that the immediate mortality from this operation is diminishing, says that in 154 operations done before 1882 the mortality was twenty-three per cent., while in 36 operations performed since, it was reduced to 8.3 per cent.

Leopold, 1887, records the following immediate results obtained by different operators: Schroeder-Hofmeir, 16.2 per cent.; Martin, 16.4 per cent.; Olshausen, 24.1 per cent.; Fritsch, eleven per cent.; Leopold, 6.2 per cent. Martin in his last 59 cases had a mortality of 8.9 per cent.; Hofmeir in last 50 cases a mortality of six per cent.; Brennecke in last 22 cases lost none.

Mialaret reports, in 1888, upon 77 operations performed by French operators, with an immediate mortality of thirty-one per cent. In those who survived recurrence took place in twenty-five per cent. within one year.

Martin, 1887, gives a summary of 311 operations performed by Fritsch, Leopold, Olshausen, Schroeder-Hofmeir, Staude, and himself, with an immediate mortality of 15.1 per cent. Of Leopold's cases, there were 24 in which some estimate could be made as to permanency of results. Among this number, 16 were free from recurrence at the end of one year, 9 after one year and six months, 5 after two years, and 2 after three years. In 33 of Hofmeir's, 20 were well after one year, 10 after one year and six months, 7 after two years, 4 after three years, and none after four years. In 20 cases of Fritsch's, 17 were well after one year, 7 after two years, and 2 after three years. In 44 of Martin's, there were 35 well after one year, 32 after one year and six months, 25 after two years, 20 after three years, 5 after four years, 3 after five years, and 2 after six years.

Secheyron, 1888, compares the results obtained by French and foreign operators (the latter including German, Russian, English, and American) as follows:

	French, 105 cases.	Foreign, 394 cases.
	Per cent.	Per cent.
Immediate mortality of operation	23.80	15.47
Death from recurrence in	18.80	..
Establishment of recurrence in	23.75	1.80
Recurrence after six months in	8.75	66.43
" " twelve months in	15.00	33.91
" " eighteen months in	7.50	20.97
" " twenty-four months in	5.00	18.18
" beyond this in	3.75	10.48

Terrier, 1888, gives his personal results. Eighteen operations, with an immediate mortality of twenty-two per cent. Four of remaining 14 cases incomplete. In 11 cases left there was recurrence in 7, at sixteen months, six months, four months, four months, three and a half months, three months, and one month, respectively. No recurrence in 4 at two years and nine months, one year and nine months, one year, and nine and a half months after operation, respectively.

Richelot, 1888, reports 13 operations, of which 2 were incomplete. In the remaining 11 there was recurrence in 5, and others are not beyond the danger period.

Fritsch, 1887, records 62 total extirpations performed by himself, with seven deaths. Of the remainder, 10 continued well at one year to one year and ten months; 1 at one year and eleven months; 2 at two years; 1 at two years and three months; 1 at two years and four months; 1 at two years and seven months; 1 at three years and one month, and 1 at three years and two months.

Post, in a series of 722 collected cases of vaginal hysterectomy, found a mortality of twenty-four per cent.

Dudley, 1887, reports that in 66 operations performed by American operators, 23 resulted fatally, while 43 patients survived and remained well for periods varying from three months to three years.

In conclusion, let me insert the statistics given by Hofmeir, and quoted by Lusk and others, illustrating the comparative advantages of supra-vaginal amputation and vaginal total extirpation.

Supra-vaginal amputation, 136 operations with 10 deasth (mortality, 7.4 per cent.), and 47 recurrences within one year. Total extirpations, 74 operations with 12 deaths (mortality, 16.2 per cent.), and 13 recurrences within one year. The ultimate results can thus be shown;

	Patients operated upon by supra vaginal amputation.	Patients operated upon by vaginal hysterectomy.
	Per cent.	Per cent.
Remained well at end of first year	51.0	63.6
" " " second year	46.0	24.1
" " " third year	42.0	26.0
" " " fourth year	41.3	Not one alive.

Many of the total extirpations, which appear in the above statistics, were performed for cancer of the body of the uterus. It was found impossible to eliminate from the whole number those which were done for cancer of the body alone.

George Woodruff Johnston.

UTERUS: INVOLUTION; SUBINVOLUTION; SUPERINVOLUTION. Involution.—Involution is the process of retrograde metamorphosis by which the puerperal uterus returns from its condition of physiological hypertrophy to the normal non-gravid state. There is a broader sense in which the word is occasionally used, including those cases of reduction in the size of the uterus following the evacuation of retained contents, as in physometra, hydrometra, or hæmatometra, or after the removal of submucous fibroids, uterine hydatids, or other tumors accompanied by hypertrophy. The process in each case is identical, but the latter conditions are relatively so rare that it is best to disregard them and use the word in its relations to pregnancy only.

Every writer upon the subject calls attention to the wonderful nature of the change which occurs. Striking as is the alteration effected in the uterus during the nine months of gestation, by which its weight is augmented twenty-one to twenty-four times, even more remarkable, if possible, is the process of involution by reason of its great rapidity. The increase in size of the uterus is due almost wholly to hypertrophy of the individual muscular fibres, together with the development of new fibres from previously existing embryonic cells, this latter process being probably confined to the inner layer of the muscular wall, and occurring wholly during the first six months of pregnancy.

At the completion of labor the uterus becomes reduced to the smallest possible bulk by the combined contraction and retraction of its walls, the blood-supply is suddenly cut off to a very large extent, and as a result, the process of growth and development gives place to one of fatty degeneration. By this means the muscular fibres are gradually transformed into fat, which is in turn removed by absorption, or by being directly cast off in the lochial discharge. Whether the muscular tissue is thus wholly destroyed to be replaced by newly developed fibres, or whether a part of the existing fibres simply undergo atrophy and still remain a component part of the diminished uterus, is an open question, but the weight of testimony is in favor of the former view. As the organ becomes infiltrated with fat it loses its deep red hue, assuming a strongly yellowish cast. At first almost stony in its hardness during the periods of contraction, it rapidly becomes so soft and inelastic as to be readily perforated by a careless examiner.

Not until the fourth week after labor can the process of regeneration be detected, and then there appear, everywhere throughout the fatty mass, new cells which develop into muscle-fibres and form a new uterus out of the wreck of the old one. The blood-vessels, both arteries and veins, participate in the process of fatty degeneration and atrophy. The mucous membrane is almost wholly shed at the time of labor, and hence has little part in the general retrograde change. It has been claimed, indeed, that it is completely stripped off at the time of labor, leaving the muscular tissue as absolutely bare as does the surgeon's knife; but this view is manifestly incorrect, the membrane remaining almost intact at the placental site, and the deeper layers covering the remainder of the surface. From these fragments of a mucous membrane the new one develops, the regeneration, according to Leopold, being practically complete at the end of six weeks.

It would seem that, concerning so universal and carefully observed a phenomenon as involution, there need be no difference of opinion as regards the rate of its progress and the time of its completion, and yet absolute knowledge of the matter does not exist. The modifying conditions are so numerous, and the methods used by which to arrive at conclusions so various, that no two observers appear to agree. Pathologists judge from appearances found after death, clinicians from the relations of the fundus to the symphysis pubis, statisticians from measurements made either with the pelvimeter or with the intra-uterine sound. Sources of error only too readily creep into the observations in each case, and seriously affect the deductions. Post-mortem examination furnishes, of course, positive results, and yet who can say how much the retrograde process has been interfered with, in any given case, by the illness causing death, or by the other attending circumstances during life? The relation of the fundus uteri to the pubes may depend more upon the amount of prolapse, version, or flexion, the fulness of bladder and rectum, the size of the pelvic cavity, and tension of the abdominal walls, than upon the size of the uterus. It has seemed to me that measurement of the vertical diameter of the uterus by means of a pelvimeter must be unreliable, by reason of uncertainty as to the thickness of the abdominal wall, and as to the importance of existing flexion, and of longitudinal compression resulting from the necessary expenditure of force.

Unquestionably, the best results must be looked for from the actual measurement of the depth of the uterine cavity in a large number of normal cases, at intervals, during the puerperal month. Much has been done in this line of investigation, and yet I know of no results which are at all satisfactory or conclusive. Up to eight or ten years ago, it was taught that reduction in the size of the uterus was most rapid during the second week after delivery, but that not until the end of six weeks or two months was the normal size regained, and this statement was regarded as authoritative until the appearance of a series of intra-uterine measurements,[1] begun by A. D. Sinclair and continued by W. L. Richardson, both of Boston. From these figures there has frequently been deduced the conclusion that involution is much more rapid than was formerly believed, and teaching has been modified in accordance with this belief. This conclusion has been partially corroborated by Charpentier, though his averages are materially larger than those of Sinclair; and Skene, in his recent work, accepts it completely.

Now, were the question at issue merely one of scientific interest, having no important practical bearing upon the management of the puerperal state, it would not properly arise for discussion in this paper, but it has a very vital connection with the vexed questions as to how long a patient should keep her bed after delivery, and how much latitude should be permitted her in resuming her customary avocations; and it has also a plain relation to the remaining topics to be considered under this heading. This being the case, it is not out of place here to call in question the accuracy * of the reported measurements, and to assert that the old belief, founded upon post-mortem investigation, is the correct one, the one upon which all rules of conduct should be based. The reason for so confident an assertion is the knowledge that the measurements, as reported in the papers above mentioned, vary more with the skill and boldness of the house physician in passing the sound, than with the condition of the patient or the duration of her puerperal period. A part of those published were made by myself, and, though septicæmia was rife in the hospital at the time, they evidenced a most phenomenal involution, amounting in some cases to superinvolution. These results I knew to be untrustworthy, and yet they corresponded with the work of my predecessors.

I was succeeded in this line of work by Dr. W. J. Otis, who, believing with me that his sound rarely reached the fundus, and fearing to do injury to a soft and friable uterus by the employment of greater force, entered upon the use of a Jennison elastic sound, to which he adapted a sliding marker or guide. With this soft and elastic instrument, used with gentle yet persistent manipulation, the whole aspect of the figures at once changed, and from that time on only once did the measurement fall below three inches. He has very kindly furnished me with the results of his examination in thirty cases, after the adoption of the new instrument, and from his figures I select the following as indicative of the general conclusion. Of the 30 uteri, 6 had a depth of three inches, 5 of three and a half inches, 4 of three and three-quarter inches, and 7 of four inches. The average depth was 3.63 inches, and the average day of measurement was the seventeenth.

I learn from the house physicians of more recent years, that the depth of the uterus always increases after a few weeks' experience in measuring, and that the figures are uniformly much greater during the service of some men than they are recorded by others. Though septic influences have been absent of late, yet the average depth, I am assured, is greater rather than less than it was found by Dr. Otis. The fallacy in this method of investigation lies in the fact that the uterus is so softened as to be easily perforated, or, at least, penetrated by the sound, thus staying the examiner's hand through fear; is often flexed; is not yet lined by normal mucous membrane, but by a soft exudate in which the instrument is readily entangled; and that upon its inner surface is an elevation corresponding to the placental site, an elevation sufficiently great to obstruct the passage of the sound. The custom of examining upon the back tends to increase existing difficulties, so that I believe the fundus is by no means always reached, even by the most skilled observer, and under the most favorable conditions.

The questions as to the influence upon involution of normal lactation, and of the routine use of ergot after delivery, are eminently practical ones, and deserving of notice. It would seem that so physiological and essential a process as suckling ought to have a favorable influence, especially in view of the intimate relation existing between the breasts and the uterus, any excitation of the former stimulating contractions in the latter. Yet this view is opposed by many observers, notably among the French. Tarnier takes conservative middle ground, hold-

---

* Since the completion of this article my attention has been called to a very important series of measurements reported by Hansen, in the Zeit. f. Geburt. u. Gyn., 1887, a review of which by Parvin appears in the Annual of the Universal Medical Sciences for 1888. He examined 200 women, making in all 1,048 sound measurements. He announces that "the duration of involution was in general ten weeks; the shortest period observed was four weeks, and this in only one case, while the longest period was three months, which was observed in four women." Parvin concludes by stating that "one of the most important practical lessons to be learned from the investigations of Hansen is, that obstetricians should insist upon a longer rest for the puerperal woman. When we remember that many a woman is up and at work two or three weeks after childbirth, and that even those whose circumstances in life do not require labor, are frequently participating in social pleasures and fatigues at the end of six weeks and two months, we can easily understand why disorders of the genital organs not infrequently result."

It was also found that involution was delayed in those who did not nurse.

ing that "the individual conditions have a much greater influence upon the course of uterine regression than lactation." In the face of such contradictory truths the chances are that Temple is correct, and the influence of nursing is a factor of minor importance. My own belief is that it is favorable rather than otherwise, provided, of course, that the patient has sufficient strength and vigor for the physiological performance of the function. Under other circumstances the drain might easily result in such physical deterioration as to materially interfere with the involution of the uterus.

Unquestionably, it is the custom of the majority of American physicians to administer ergot, as a routine measure, at the close of labor. Subsequently, should the uterus fail to contract firmly or regression prove tardy, the exhibition of the drug is continued with anticipation of benefit. Of late years, however, the wisdom of these procedures has been disputed by those who believe not only that the practice is useless, but that it is actually harmful, it being claimed that involution is retarded thereby. This theory, while given a respectful hearing, has not as yet found favor in practice, the sanction and approval of the profession being still given to the use of ergot as outlined above.

Among other factors in determining the rapidity and completeness of involution are the duration of labor and amount of resultant fatigue; the condition of the patient's health before labor; the occurrence of lacerations of cervix or perineum; the occurrence of septic poisoning, or of local inflammatory conditions from any cause. These matters will receive more especial mention in the consideration of subinvolution. After abortion or miscarriage, unfavorable conditions being absent, involution proceeds as after normal labor, only more slowly.

SUBINVOLUTION.—Subinvolution is simply a state of persistent incomplete involution, the process having by some means been arrested before the uterus has fully regained its normal state. Corresponding with the intensity of the acting cause and the time of its occurrence, the uterus may remain very large, as at the close of the first week, or it may be only moderately hypertrophied. From this fact probably has arisen much of the uncertainty which still exists as to the exact nature of the condition and of the subsequent changes which take place. So great, in fact, is this uncertainty that few writers can agree even upon a name which suitably indicates the nature of the disease; those who make use of the term "subinvolution" acknowledging that it is only clinical in its application and by no means covers the progressive pathological changes; those who classify it under the heading "chronic metritis" for the most part disclaiming any belief in its inflammatory origin or course; and the terms "engorgement" and "infarctus" indicating only phases of, or steps in, the progress of the disease. "Chronic parenchymatous metritis" is open to the same objection as "chronic metritis," because suggesting inflammation. Thomas, in absolutely denying any inflammatory element, suggests and uses the title "areolar hyperplasia," as descriptive of a condition of the uterus of which subinvolution is by far the most frequent cause, thus considering the latter not as a separate disease, but rather as a merely fugitive condition giving rise to "areolar hyperplasia."

However, it matters little what one chooses for a name, if only he recognizes the fact of arrested involution and acts accordingly, as witness the statement of Hart and Barbour:[1] "The term subinvolution is convenient, and simply expresses the mode, the most important, in which the condition to be described (chronic metritis) is produced. Apart from the history, it is not possible to diagnose between a subinvoluted uterus and one enlarged from chronic metritis alone. Further, the condition of subinvolution is maintained by the process of chronic metritis, that is, by the formation of connective tissue which takes the place of the fattily degenerated muscular fibre. Finally, the treatment is the same in both cases." In other words, whatever the conditions in the early stages of the disease—whether involution has been arrested in the first puerperal week by septic absorption, with a resultant uterine or periuterine inflammation, or in the fourth week by a mechanical displacement—there results sooner or later, in consequence of continued hyperæmia and irritation, a proliferation of connective tissue, with ultimate contraction and hardening of the whole uterine mass. These later stages constitute the "chronic metritis" or "areolar hyperplasia" above mentioned.

As regards the method by which the normal enlargement is perpetuated, there are at least two definite and diametrically opposed views, both of which, as has already been intimated, may be consistently held to be correct. Courty says:[2] "The hypertrophy of the uterus by failure of the retrograde evolution is a pathological hypertrophy by its permanence, but resulting from a purely physiological hypertrophy in its origin." He quotes West as claiming a fatty change with lack of absorption of the product, and claims the contrary to be true. He states that there is not a change in the texture of the uterus but a "persistence in the number and volume of its component elements. There is not a fatty change of the uterus," but an hypertrophy by excess of nutrition.

On the other hand, Hart and Barbour state that "the condition of permanent enlargement of subinvolution is not due to the non-degeneration of muscular fibre, but to the substitution of connective tissue for the products of this degeneration."

In view of this difference of opinion, and in the lack of positive testimony on either side, it is fair to infer that subinvolution is produced in both ways, the precise process being determined in any given case by the acting cause. In either case the final result would be the same, the method of its production having been minutely described by Dr. Mary Putnam-Jacobi[3] as a structural alteration in the walls of the enlarged blood-vessels, "in virtue of which nutritive transudations of an albuminous plasma took [*take*] place, which gradually caused [*cause*] a local development of connective tissue (perivascular sclerosis)." This process she claims to be inflammatory in its nature.

Etiology.—In entering upon the subject of the causation of subinvolution, we are at once in a wide and important field for discussion—wide because of the multiplicity and variety of the causes alleged; important because of the necessity for their recognition and consequent avoidance or removal. The first and most fruitful source of subinvolution is without doubt laceration of the cervix. There are some who still dispute this fact, but their number is rapidly growing less, and it is to be hoped that before many years there will be as great unanimity in asserting the necessity for closing lacerations of the cervix uteri, as there is now in urging repair of the perineum after injury.

The testimony of Emmet in this matter may be considered somewhat biassed, yet the accuracy of his observation and the truthfulness of his statement can hardly be called in question. He says:[4] "In closing this brief chapter I would state that, for many years past, I have met with few or no cases of subinvolution which were not due to laceration of the cervix." T. A. Reamy, in the "American System of Gynecology," pointedly remarks "that if a laceration of the cervix is observed, more or less subinvolution, either of the whole uterus or of the cervix alone, is almost absolutely certain."

The means by which the result is produced is not difficult to understand. In the first place the presence of an open wound, and later on, either a mass of cicatricial tissue or an everted and eroded surface of mucous membrane, serves as a constant source of irritation to keep up an active hyperæmia of the uterus. However, in the early weeks the very effort of nature to repair the damage is opposed to the process of involution, and subsequently, as the wound remains and the irritation persists, the permanence of the hypertrophy is insured by the development of an endocervicitis and endometritis. It is not necessary that the laceration should be a large one, for even very superficial tears, if exposed to the deleterious influences of an irritating vaginal discharge and denied by the restlessness or too early effort of the patient the quiet needed for repair, may fail to heal kindly, and so produce the same result as the deeper lesions—at least so far as our subject is concerned.

Septic absorption is, without question, a far more frequent cause of subinvolution than will be admitted by the mass of practitioners, and a present shame it is, in this age of preventive medicine, that this statement should be true. Not that in every case of subinvolution due to this cause, there should have been a well-marked run of "puerperal fever" so-called; but where antiseptic, or at least aseptic, methods are despised or neglected, nothing is more common than to have, during the first week of convalescence, a rise of two or three degrees in the temperature (commonly called milk fever), the presence of fetid lochia, and moderate abdominal tenderness. In many of these cases there is set up a sufficient degree of uterine or periuterine inflammation to interfere seriously with the process of involution; and if this be true of these mild cases, much more surely will subinvolution follow the more marked instances of septic intoxication. Given a case of puerperal septicæmia, and subinvolution may be confidently predicted.

The next cause to receive attention ought perhaps to have been given precedence over the last. It is the faulty management, or rather the mismanagement, of the period of convalescence; and by mismanagement I mean the permission of too much freedom in movement and of too early rising. I am well aware of the fact that patients are not only allowed to be up and dressed before the end of the first puerperal week, but that such a course is even advised by men who are otherwise safe and skilful practitioners and good observers. That the reasons they give for such a custom have some weight is not denied, but it is far from true that the custom is either a safe or a desirable one. The general weakening and loss of tone of the muscular system, due to a stay in bed of three weeks' duration, is far more than compensated for by the complete rest of the nervous system and the diminution in size of the soft and heavy uterus. The emptying of the uterus and vagina of clots and lochial discharge can be better accomplished by ergot and a douche, than by sitting up upon a chamber vessel or chair, as advised and practised by Goodell, and without the danger of the latter course.

J. T. Johnson,[6] referring to the fact that the colored women of the South who rose quickly after labor are supposed to prove not only the lack of danger, but the benefit of the custom, gives the result of his experience at a Freedmen's hospital, after the late war, in the following words: "Patients suffering from the effects of subinvolution, uterine displacement, and hæmorrhage, presented themselves more frequently than for any other ailments." "While some women are undoubtedly benefited by an earlier sitting up than the customary nine days, . . . many women, and perhaps the majority, are injured by it."

The way in which subinvolution is caused by early exertion, and especially by a too speedy assumption of the upright posture after labor, is by the production of displacement of the uterus, prolapse, version, or flexion, and consequent interference with the local circulation, and hence, with the process of fatty change and absorption. The uterus remaining large, the displacement continues and increases, the hyperæmia is perpetuated, and the chronic changes already outlined proceed to their full accomplishment. By far the safest course is to take conservative ground, and insist upon a sufficiently prolonged rest in the horizontal posture to permit of a near approach of the uterus to its normal size, and then to make a gradual and cautious return to the ordinary habits of life. The rule of Tarnier is a good one, and certainly does not err on the side of conservatism. Provided the uterus cannot be felt above the pubes, the lochia are no longer bloody, and no fever exists, he permits his patients, between the fifteenth and twentieth days, to be moved to a reclining chair where at first they remain only one hour. Lengthening the time by one hour daily, in three or four days they are ready to try a few steps, and so gradually to gain power to walk without fatigue or injury.

Very painful and tedious labors, by leaving the patient in a state of complete exhaustion from which recovery is slow and uncertain, are probably not infrequently the cause of subinvolution. In this case there is a lack of tonicity in the vessels, the active process of removing the waste and building up the new uterus is imperfectly carried on, a passive hyperæmia persists, and the disease is gradually developed. Severe hæmorrhage, either before or after delivery, would act in the same way, by lowering the vital powers and by diminishing the oxidizing properties of the blood.

Various other causes have been suggested, such as incomplete emptying of the uterus at the completion of labor, the presence of tumors in or about the uterus, and sexual excitement due to too early intercourse, or even to sharing the same bed by husband and wife. This latter cause has doubtless caused not a few cases of puerperal hæmorrhage, and can therefore be suspected of setting up a sufficient amount of pelvic congestion to render subinvolution liable.

As predisposing causes may be mentioned a poor state of health from whatever cause, frequent and rapidly recurring pregnancies, and abortions.

Frequency.—For some years after Simpson first called attention to the "Morbid Permanence of the State of Puerperal Hypertrophy," occasional cases were reported from various quarters, but the condition was considered as an infrequent sequel to pregnancy. Of late years, however, with improved methods and more exact knowledge in the matter of gynecological diagnosis, subinvolution is found to be one of the commonest of the morbid results of child-bearing. If it be true that the above-mentioned causes are apt to produce a "morbid permanence of the state of puerperal hypertrophy," then it is by no means to be wondered at that subinvolution is a frequent condition among parous women. It is impossible to give statistics of any value on this point as, in the nature of the case, they must vary materially in the practice of different men, in hospital and private practice, also because of the confusion in nomenclature and classification.

The condition once established, from whatever cause, it tends to the more intractable, and oftentimes incurable, disease already referred to as chronic metritis, or areolar hyperplasia; hence the importance of the early recognition of the danger, that the cause may be removed and complete involution secured at the proper time. This point will receive more particular consideration under the head of treatment.

Symptoms.—The symptoms of subinvolution are, as a rule, vague, and rather suggestive than indicative. Commonly backache and a tired feeling, either continuous or arising upon slight exertion, first call attention to the existing trouble. Often such patients come desiring some simple tonic, hoping thus to escape their feeling of lassitude. Menorrhagia and metrorrhagia, much less frequently amenorrhœa, are apt to be present, the former being at times so excessive as to produce a profound state of anæmia, and even threaten life. When this occurs it is usually a result of the coexisting disease of the endometrium. Dysmenorrhœa by no means always exists, though it is frequently present. If the uterus is very large, symptoms arise from the mechanical effect of pressure, such as difficult or painful micturition, constipation, and hæmorrhoids. Pain may be experienced in more remote parts, as in the thighs, calves of the legs, under the breasts, or in the head.

On examination, the uterus is found to be uniformly enlarged and, if the disease be of recent development, softened. The cervix is commonly lacerated, the canal large, sometimes even admitting the finger. Pain is not so marked as later in the course of the disease, yet firm pressure anywhere upon the uterus shows it to be much more sensitive than normal. On account of the increased weight of the organ it is partially prolapsed, often resting upon the floor of the pelvis, or in a position of retroversion.

Diagnosis.—It is by no means a simple and easy matter to make a positive diagnosis in any given case, unless the patient has been under continuous observation since the pregnancy from which the condition dates, for the reason that the term is rather expressive of a clinical fact than of a pathological process. The uterus may have undergone a perfect involution, the hypertrophy developing subsequently as a result of an endometritis, of a displacement, or of ovarian disease. A probable diagnosis may, however, be made in most cases by a careful comparison of the symptoms and physical signs, the former having dated from a previous confinement or from a period not long thereafter.

On account of the softness and moderate sensibility of the uterus in many cases, it may be mistaken for pregnancy in the early weeks, or vice versa. In case of doubt, it is far better to wait for time to indicate the true diagnosis than to run the risk of producing abortion by passing the sound. This word of warning is not an idle one, for the accident has often happened to the impatient and thoughtless, and should be guarded against by excess of caution. It is not impossible that the two conditions may coexist; hence arises additional cause for care.

In view of the uncertain relations existing between subinvolution and chronic metritis, and because, if they be separate diseases, the treatment of each is the same, it is hardly worth while to attempt a nice discrimination. If the disease be subinvolution pure and simple, with no metritis or "perivascular sclerosis" grafted upon it, the uterus will be softer and more doughy than normal, will measure three inches or more in depth, and pressure upon it will be easily borne. Where there exists the condition described as chronic metritis or areolar hyperplasia, the uterus is hard and sensitive; there is usually more or less constant pain in the hypogastric region. The uterus is movable in both instances, unless there be adhesions or accompanying perimetritis.

Fibroid tumors increase the bulk of the uterus and elongate its cavity, but they can almost always be felt as local enlargements of the uterine mass, or at least the enlargement is not uniform. The history of the case will usually fail to show any causative relation of pregnancy. The appearance of the cervix will often be of assistance, it being usually of normal size and density in the case of tumors wholly confined to the uterine body. Malignant disease confined to the body might be mistaken for subinvolution on account of the tendency to hemorrhage, the uniform enlargement, the lack of pain, and the absence of sensitiveness commonly noted in the early months. The age of the patient, the continual presence of a watery discharge, and sometimes the offensive odor, together with the wasting strength, should suggest the nature of the disease, and microscopic examination of shreds removed by the curette will determine it.

Prognosis.—The prognosis of simple subinvolution which has not yet progressed to the sclerotic stage is good, provided suitable treatment be adopted. Untreated, its tendency is to run through the several stages of fibrous deposit, induration, contraction, atrophy. Under these conditions its course is very variable, being influenced by a great number of factors. In some instances the complete course outlined above appears to have been run through inside of a year, yet on the other hand there are cases which seem to remain almost stationary for years. When the stage of fibrous infiltration has been reached—and most cases presenting themselves for the relief of symptoms have already entered upon it—the prospect of complete cure and restoration to the normal is poor. As a rule, the most that can be expected is the relief of the principal symptoms, partial reduction of the existing hypertrophy, and the avoidance of more serious complications. The uterus may also be placed in a more favorable condition for the occurrence of pregnancy, and for its successful completion.

Treatment.—To a very considerable extent subinvolution is preventable, and hence prophylactic measures should be first considered and uniformly practised. It is unnecessary to urge the importance of seeing to it that every woman approaches her confinement in the best possible state of health. Of course existing disease will be combated and removed so far as possible, but let the physician also set his face against every depressing influence so often invoked by women to diminish the size of the fœtus and so insure an easier labor. Let good food, fresh air, and plenty of exercise be invoked to aid in establishing or continuing a condition of vigorous health previous to delivery.

The importance of insisting upon a recumbent posture and absence of effort during the first two weeks, and upon a gradual and cautious getting up after labor, has already been referred to.

Septic causes having much to answer for in the production of the disease in question, they must by all means be guarded against. And with the present light upon the subject of antiseptic midwifery, there is no excuse for the man who neglects such simple precautions as are universally agreed upon. In this connection Goodell[1] says: "The day is surely coming when to have a case of puerperal fever in one's private practice will be deemed a crime."

Tedious and very painful labors being, by their exhausting influence, potent factors in causing or at least in favoring the occurrence of subinvolution, they should be avoided so far as possible by the use of forceps and of the various anæsthetic agents. Chloral during a long first stage is capable of giving rest and relief from pain, with proportionate lessening of exhaustion. Ether and chloroform properly used are perfectly safe, can be given, if necessary, for long periods without material delay in the progress of labor, and even with the effect of shortening the duration in many cases, with diminished rather than increased risk of hemorrhage, and with the result, in almost every instance, of great relief of suffering, a minimum of fatigue, more speedy convalescence, and more rapid and certain involution. There is no need of commendation of the forceps, yet, bearing in mind the baneful influence of an unnecessarily prolonged second stage, no mere prejudice against operative interference should be permitted to prevent the timely employment of this means of abridging wear and tear.

Lacerations of the cervix having been shown to result almost inevitably in subinvolution, it follows, as a corollary, that the presence of such tears should always be sought for after labor, in order that this and other possible consequences may be averted by suitable treatment addressed to the lesion. Conversing with a successful fellow-practitioner recently upon this subject, I was assured that not one physician in a hundred makes a practice of examining his patients during or at the close of the puerperal month, and that such a custom is uncalled for. If this belief is general and the former assertion correct, and I believe them so to be, the frequency of subinvolution is to a large extent accounted for. He is a bold man who will fly in the face of such unanimous testimony as now exists to the contrary, and assert that laceration of the cervix is not liable to result in subinvolution, or that it matters not if it does, as the latter condition is one of no importance; yet one of these positions must be taken by the man who disbelieves in the practice of examining his puerperal patients before permitting them to pass from his hands. Unless some special symptoms seem to demand interference, it is well not to examine until after the completion of the second week, and better still is it to wait until the close of the third week, or even of the puerperal month. By this time involution should be well advanced, and the cervix should have returned nearly enough to the normal to enable one to judge well as to the extent of any laceration, should one be present. The treatment of such lacerations needs no consideration here, that having been fully covered in another article; but the importance of caring for them at once cannot be too strongly enforced.

In making the examination as recommended, any other existing condition which may serve as a possible cause of trouble can be noted and receive due attention. It is taken for granted that any rupture of the perineum has been previously sutured, but the success of the operation is now to be assured. If the uterus is displaced, it must now be returned to its normal position and sustained there by glycerine tampons or a pessary.

When subinvolution is discovered soon after labor, simple removal of its causes will usually suffice for a cure. Later on, when the patient applies for treatment for the relief of symptoms, the problem is by no means so simple. Measures directed toward the elevation of the general tone of the system are always called for. Tonic remedies, liberal diet of the right sort, general sponging followed by brisk rubbing, and, in those cases in which suitable exercise cannot be taken, the employment of massage, are to be advised. Having at the same time removed all existing local conditions which may serve to perpetuate the disease, our efforts must be turned more directly to the removal of hypertrophy and restoration of function of the diseased organ.

In almost all cases there exists hyperæmia, which is, indeed, the important element in the continuation of the trouble. This should be attacked by puncture, scarification, or, better still, by the application of leeches to the cervix, and by the use of glycerine tampons and hot douches. The latter must be given properly in order to be of any value, the position being on the back with hips raised, the water not cooler than 110° F., and the duration of the douche not less than fifteen minutes. Painting the cervix with Churchill's tincture of iodine can do no harm, and is often of great benefit. In those cases in which the cervical canal is patulous, and active endometritis is absent, the application of iodized phenol to the uterine cavity by means of an applicator is of marked utility. Such an application should be made about once a week.

Electricity is highly recommended by many writers of recent years, and has given good results where other means have been tried in vain. Both the galvanic and faradic currents are of value, either separately or in combination. The faradic current is chiefly applicable, in recent cases, to promote contraction of muscular fibre and diminution of hyperæmia by the resultant emptying of the venous circulation. The galvanic current finds its most important application in the later cases, in which fibrous deposit has already taken place. Galvanic stem-pessaries have been recommended, but not being altogether safe, and being of rather doubtful utility, they have never found much favor. They can probably be dispensed with.

Not infrequently there coexists with, or springs up in consequence of, subinvolution, a condition of hyperplastic endometritis, which is largely accountable for the hæmorrhagic symptoms. In such cases it may be necessary to remove the diseased membrane by the use of the sharp curette, following it, in intractable cases, by the application of tincture of iodine, or even of iodized phenol. This, of course, is to be regarded as a surgical operation, strict antiseptic precautions being observed, and the patient being confined to bed for several days thereafter.

In some refractory cases of subinvolution, operative interference has been practised by Reamy and others, in "removing a wedge-shaped piece from the cervix, and closing the rent with sutures as in trachelorrhaphy, . . . when laceration of the cervix did not exist." Good results are reported from this operation.

Subinvolution of the Vagina.—In the vagina, as in the uterus, the process of hypertrophy and development continues throughout pregnancy, to be followed after delivery by a process of involution almost identical in its method and purpose with that which occurs in the uterus. By this means the vagina is restored, in about two or three months, very nearly to its normal nulliparous condition, remaining permanently, however, a little larger than before. This perfect result is, unfortunately, by no means always accomplished, and subinvolution of the vagina is, like subinvolution of the uterus, of common occurrence.

The causes of incomplete involution of the vagina are, for the most part, those that have already been assigned as factors in the production of uterine subinvolution, the latter almost always being accompanied by more or less vaginal subinvolution. The cause which most uniformly and certainly interferes with the process of involution in the vaginal walls is, without doubt, laceration of the perineum or pelvic floor. While laceration of the perineum in its entire thickness is common, laceration of the posterior vaginal wall, together with the inner portion of the perineal body, is, if possible, a still more frequent accident, and is followed by more disastrous results. When a rupture extends through the fourchette, and even more deeply into the skin of the perineum, the injury cannot fail to be noticed by the most casual observer; but when internal inspection is necessary to disclose the rent the chances are strongly against its discovery. The average physician considers his duty done when he inspects the perineum externally, and to his great satisfaction finds that "not even the fourchette is torn," forgetting or not knowing the fact, so strongly insisted upon by Mathews Duncan, that the point at which laceration usually, and in primiparæ almost inevitably, begins is at the ostium vaginæ, not at the ostium vulvæ—at the plane of the hymen, not at the fourchette. In examining the perineum after labor, therefore, look carefully to the mucous surface.

Prophylactic methods of treatment will be the same as outlined above for subinvolution of the uterus, especial stress being laid upon the care of the perineum both during and after labor. Curative treatment, after known or possible factors in the production of the disease have been removed, will consist in the use of douches, occasional applications of iodine, with insertion of glycerine and alum tampons, and the employment of electricity. While both the faradic and galvanic currents are of utility, and many prefer the latter, my own preference is strongly for the former. By using a bipolar electrode active contraction of the muscular fibres is brought about, their tone is thereby improved, passive hyperæmia is removed, absorption is stimulated, and the uterus is more firmly supported.

Operative interference is often called for to repair old injury to the perineum or cervix, to remove cystocele and rectocele, or to narrow and shorten a redundant vagina, which, by the simpler means mentioned, cannot be reduced to the normal.

SUPERINVOLUTION.—Nominally superinvolution is an excess of involution, by which the uterus is reduced to less than its normal size, yet it is an open question whether just this process really occurs. Undoubtedly cases are noted, and with increasing frequency, in which, at some time after the completion of puerperal convalescence, the uterus is found in a state of atrophy; but is this atrophy due to excess of the normal process with failure in the regeneration of muscular fibre, or is it rather fibrous contraction following upon actual inflammation or occurring as a sequence of subinvolution, or is it even a result of disease of the ovaries by which their function is destroyed, and hence corresponding to the senile atrophy of the menopause? The present attitude of the profession toward this disease is one of observant scepticism. It is too soon for anyone to assert dogmatically that superinvolution, pure and simple, does not exist; yet before making that diagnosis in any case it would be well to consider carefully if there be not some other disease, of which the atrophied uterus is merely an expression or consequence. Even the classical case of Simpson—the case which first suggested to his mind the title under consideration—is more likely one of premature atrophy and cessation of function due to tubercular disease.

But whatever opinion may be held concerning the accuracy of the term, it must be admitted by all that uterine atrophy does occur, without apparent cause, in a certain number of cases, not long subsequent to delivery, and to this condition has rightly or wrongly been given the name superinvolution. That the condition is a rare one is shown by the scarcity of reported cases, and by the fact that most writers upon the diseases of women ignore the subject completely.

As regards the pathology of superinvolution, it can only be said that the uterus resembles that organ in a state of senile atrophy. Observations are too few to afford any definite information concerning the morbid processes involved.

There are no distinctive or constant symptoms which belong to the disease, with the single exception of amenorrhœa, or scanty menstruation. Besides this, there is the ordinary train of symptoms common to many another form of uterine disease. Examination reveals simply a non-sensitive uterus, of less than the normal size and depth. The ovaries, if found at all, are commonly much smaller than normal, and are not infrequently bound down and compressed by adhesions.

The disease is a very intractable one, though the prognosis will vary in accordance with the pathological conditions which stand in causative relation to the atrophy. In some cases, diagnosticated as superinvolution, a cure has been achieved and pregnancy has followed, but it may be laid down as a fact that most cases will prove absolutely rebellious to treatment and sterility will be permanent.

The only treatment which has been found of value is one having for its purpose stimulation of the uterus, and this is best accomplished by the combined use of moderate cervical dilatation and electricity. Either a Hanks or a steel-branched dilator may be used to stretch the cervix slightly every week or ten days. Rockwell recommends that both the faradic and galvanic currents be utilized, and relates one case in his own practice in which menstruation was thus induced in a uterus measuring but one and three-quarters inch. The poles of the faradic battery may be used indifferently, but when employing the galvanic current he advises that the negative pole be placed within or against the uterus.

Rufus A. Kinsman.

UTERUS, PROLAPSE OF THE.

The subject of uterine prolapse, embracing as it almost necessarily does a consideration of hypertrophic elongation of the cervix and prolapse of the vagina, is very complicated. Before considering it in detail, it will be necessary to define as clearly as possible what the normal position of the uterus is, and how it is maintained. Under normal circumstances the uterus is supposed to occupy a position of anteversion, the fundus resting upon the bladder, and the cervix pointing backward toward the tip of the coccyx; it is kept from sinking by the resistance offered from below, and by certain ligaments of which I shall speak very briefly. The broad ligaments are folds of peritoneum, which divide the pelvic cavity into two parts, an anterior and a posterior, and which cover the body of the uterus, passing outward and backward to the sides of the pelvis; these ligaments contain connective tissue, vessels, nerves, and muscular fibres. The utero-sacral ligaments are folds of peritoneum containing muscular fibres and connective tissue; they pass outward and backward, from the body of the uterus toward the second sacral vertebra. The utero-vesical ligaments are formed by the peritoneum as it passes between the uterus and bladder. Lastly, the two round ligaments extend from the external abdominal ring to the anterior and superior part of the uterus. The vagina is a mere slit in the pelvic diaphragm running from the hymen to the cervix uteri, to which it is firmly attached; the anterior and posterior walls are in apposition forming the **H** appearance spoken of by Henle; it is firmly attached to its neighboring organs and in front to the pubic arch. The fundus of the uterus enjoys almost perfect freedom of motion, rising and falling with a full and empty bladder, the ligaments limiting excess of motion only. Savage, in experimenting on artificially produced prolapse, a vulsellum being attached to the cervix and traction made in the direction which the uterus would take, found that about one and a half inch of descent could be accomplished before the ligaments offered resistance; then the utero-sacral ligaments became tense, but there was no sign of strain upon the broad or round ligaments. When these utero-sacral ligaments were severed, the uterus yielded about one inch more, and when the broad ligaments together with the subperitoneal cellular tissue were divided, complete prolapse resulted.

Prolapse of the uterus may be complete or partial. It is called complete when the fundus lies below the pelvic outlet.

By far the greater number of cases of prolapsus uteri date from the puerperal condition, though it may occur at any age, and in the virgin. Monro reports a case in a child three years of age. Cases of congenital prolapse have been spoken of, but are not described with sufficient detail.

Out of 174 cases collected by Wanley, there were only 6 occurring in women who had not had children. Winckel thinks that most cases of prolapse occur between the twenty-fifth and thirty-fifth years of life.

A deformed (kyphotic or spondylitic) pelvis may be the initial cause of prolapse, as may also be a very roomy pelvis. In the first case the uterus does not find space sufficient for its accommodation. Veit reports the case of a girl, fourteen years of age, who had a kyphotic pelvis and prolapse of the uterus. Long and exhausting sickness, such as typhoid fever, cholera, or phthisis, may lead to such a diminution in the amount of the fatty tissue which normally surrounds the uterus that the organ, deprived of this support, sinks down. Senile atrophy may lead to the same result. Increase in the intra-abdominal pressure, caused by long-continued coughing, straining at stool, and tight lacing, may cause prolapse. Dr. Dickinson has called attention to the increased bulging of the pelvic floor due to tight lacing; he finds that this harmful practice increases the projection more than one-third, and believes that when a large number of cases are collected he can show "that it is those women having roomy pelves, or pelves of less inclination than usual, whose pelvic floors sag most under pressure from above." He thinks that the uterus must descend with the structures above it. With a quite tight corset the displacement is one-third of an inch; this seems a very small descent; but when we consider the other factors spoken of above as producing an increase in the intra-abdominal pressure, namely, coughing and straining at stool, it is quite easy to see how this displacement can be much increased. Engel states that in every one of thirty autopsies in which evidence of tight lacing was found, prolapse was present to some degree, except where adhesions had prevented it.

Heman and Skene were the first to call attention to an undue bulging of the pelvic floor and diaphragm; they found the average displacement to be about four inches, but in some cases it amounted to more than six.

Change of position must, with the exception of the undue bulging just spoken of, precede prolapse; that is, the long axis of the uterus must come more and more to correspond with the long axis of the vagina. The cervix approaches the anterior vaginal wall, and a position of retroversion is established. Prolapse may occur suddenly after lifting some heavy object, after receiving a blow upon the abdomen, and after a fall. Anything tending to make an open canal of the vagina favors prolapse of its walls and so leads to descent of the uterus. Pessaries which stretch the vagina, masturbation, which, it is claimed, causes a loss of tonicity in the tissues, and individual peculiarities of tissues all tend to make a normally closed canal an open one, and so favor prolapse. During labor the vagina becomes an open canal or a yielding medium, and remains so for some time after birth, and the uterus is always found prolapsed immediately after the termination of labor. The vaginal walls begin to curve inward, and the parts above, deprived of this support, sink down; the peritoneum has been very much stretched and lies in folds around the uterus, only to regain its firm tone through time. If now we add to this a torn perineum, and a uterus whose normal involution has been interrupted through metritis and poor nutrition, we have all the conditions for the production of prolapse. These are a heavy uterus with lax ligaments, whose position may have changed, so that the long axes of the uterus and vagina are beginning to correspond or

do correspond; a prolapsing anterior vaginal wall, not finding the support to which it is accustomed on the perineum; and a dilated vagina whose walls may have suffered some rupture. Very prolonged labors and obstetrical operations have been supposed to be the antecedents of prolapse.

Hypertrophy of the fundus and cervix of the uterus, as well as tumors situated in the organ, *e.g.*, subserous fibroids and polypi, may so increase the weight of the uterus as to cause it to prolapse, the ligament and collum of the vagina no longer being able to support the heavier burden.

Abdominal tumors, whether or not attached to the uterus, may force it downward, or, on the other hand, they may form adhesions, and thus prevent prolapse. Ascites may displace the organ downward. The anterior vaginal wall may be prolapsed as the result of the presence of a tumor between the bladder and vagina, or of a cyst, and so indirectly lead to prolapsus uteri.

Fritsch has never seen a case in which primary prolapse of the posterior vaginal wall was the inciting cause.

Hypertrophy of the cervix, as already said, may be divided into infra-vaginal and supra-vaginal. Huguier drew attention to this condition, and said that most cases of prolapse originated from this cause. In the infra-vaginal variety the cervix rarely attains a length greater than that of the vagina. This form of hypertrophy appears to be due to greater nutritive activity; and most of these cases are traceable to the traumatisms of labor, or to defective involution. Fritsch thinks this hypertrophy is caused by displacement reducing pressure on the cervix, and so predisposing to greater activity and growth. The posterior lip of the cervix is very often hypertrophied, and has been called tapiroid, from its resemblance to the snout of a tapir. The pathology of hypertrophy of the supra-vaginal part of the cervix is a much disputed subject.

Goodale gives four of the theories advanced so concisely that I cannot do better than quote from him.

"(*a*) That the primary affection is a downward growth, a true hypertrophic elongation of the supra-vaginal portion of the cervix; and that the prolapse of the vagina and bladder is secondary, being the necessary result of the former.

"(*b*) That there is no change of structure in the cervix other than the strictly mechanical one of elongation, which is a secondary accident, consequent upon the traction exerted by a primary prolapse of the vagina and bladder.

"(*c*) Martin's, that the circular hypertrophy of the vaginal portion of the cervix, of which the eversion of the os is the result, is a disease, *sui generis*, and that it constitutes the weight which lengthens out the supra-vaginal cervix.

"(*d*) Isaac E. Taylor's, that, contrary to the commonly accepted belief, the glandular portion of the cervix during gestation is not effaced but hypertrophied, and that even after labor it still exists; for it has undergone nothing more than a momentary expansion of its canal for the passage of the fœtus; that consequently, if the natural process of involution does not take place, the gravity of this hypertrophied cervix will aid and sustain the elongation of the non-glandular part of the supra-vaginal cervix, namely, the isthmus, which is thick, soft, and ductile, in the non-involuted womb."

Savage thinks that there are no cases in which the two varieties of infra- and supra-vaginal hypertrophy exist in the same subject.

The conjunction of the theory of traction with that of ductility, traction from the prolapsing bladder and vagina, ductility from a chronic congestion of the womb, "offers a very reasonable explanation for the phenomena of uterine elongation." Winkle records 9 cases, in 1,618, in which the cervix had descended without displacing the vaginal walls.

The lower half of the anterior vaginal wall usually begins to prolapse, and with this is generally associated a condition of beginning prolapse of the bladder, and cystocele; the remaining portion of the anterior wall follows, with prolapse of the uterus later. Martin speaks of one case in which the prolapse began in the upper third of the anterior wall, and was due to a coil of intestine lying between the bladder and the uterus; it is very rare for a prolapse to begin by the bulging out of the posterior wall. A rectocele is of comparatively rare occurrence, the posterior wall usually freeing itself from the rectum, and prolapsing without it. Winkle speaks of 108 cases of prolapse of the uterus, of which 54 were associated with cystocele; rectocele was found, however, in only 33 cases.

In complete prolapse, the uterus may be either anteverted or retroverted, there is a prolapse of the vaginal walls, and complete or partial prolapse of the bladder, associated in rare cases with rectocele. The cervix may be found hypertrophied as a whole, or only its anterior lip, or the long hypertrophied cervix may be seen projecting through the vulva and felt inside with no displacement of either vaginal wall, and with the fundus uteri in very nearly its normal position.

The peritoneum usually becomes displaced with the uterus, and occupies relatively the same position that it did with the uterus normally situated in the abdomen. This relation of the peritoneum to the prolapsed organ should be carefully studied.

The symptoms of prolapsus uteri vary exceedingly. As a rule, the condition comes on slowly, occupying from a few months to a year or two in forming, and giving rise to symptoms which will be mentioned later. On the other hand, there may be great pain of a tearing character, nausea, vomiting, suppression of urine due to compression of the ureters, or loss of consciousness. Peritonitis and death may occur in other cases, although the prolapse is sudden and little complaint is made. The sudden strain to which the peritoneum is subjected accounts for the acute pain. In cases in which the prolapse occurs slowly there may be pain during defecation, dysuria, backache, and a feeling as though all the contents of the pelvis were falling out, a feeling of great fulness in the vagina, and symptoms associated with backward displacement of the uterus. Incontinence of urine Winkle found to exist in only one per cent. of his cases. Any cause which serves to change the intra-abdominal pressure, causes pain, as using the arms, etc.; standing, walking, and going upstairs are very disagreeable to the patient. If prolapse is complete the patient walks with a straddle. Menstruation may be normal, but as a rule it is scanty. Conception is possible, and one case is recorded in which the fully prolapsed uterus became pregnant.

Coition has been known to take place through the uterine orifice. Leucorrhœa is usually present when the prolapse is complete, and we may also find ulceration and erosion, which take a long time to heal. Fritsch calls attention to the rarity of malignant disease developing in a prolapsed uterus. Gangrene may occur. Adhesions between the intestine and the pelvic organs may make reposition impossible.

Diagnosis.—Only in cases of beginning prolapse is the diagnosis difficult, the patient usually, in cases of long standing, making a correct diagnosis without the aid of a physician.

Backache and bearing-down pains are usually complained of. A digital examination establishes the position of the uterus; the cervix will be found pointing toward the anterior vaginal wall, and the whole organ lower down than normal. Coughing and bearing down will force the uterus nearer the pelvic outlet, because of the increased intra-abdominal pressure, and this will help to confirm the diagnosis. If the case is far advanced when seen, the anterior vaginal wall will fall out when the patient bears down, and the posterior wall will be found, as a rule, to have descended with the uterus, which now occupies a much lower position in the pelvis. At the vaginal orifice the long axis of the uterus corresponds with the axis of the vagina, the cervix appears, then the fundus, and prolapse is complete. Cystocele will be easily recognized by introducing a sound into the bladder; likewise a finger in the rectum will inform us whether or no there is a rectocele. The relation which the vaginal walls bear to the uterus should be noted, to see whether the whole vagina has been inverted; if it has not been, then the positions of the anterior and posterior vaults should be ascertained. After excluding pregnancy, a sound can be passed into the uterus, which will tell us the length of the cavity, and by feeling carefully the sound as it passes the internal os, we can determine how much of the depth is due to hypertrophy of the cervix in those cases in which the uterus is found larger than normal. One or two fingers introduced into the rectum, the other hand upon the abdomen, will give us information regarding the position of the fundus. If the prolapse is not complete, reposition should be tried, first of the anterior vaginal wall, then of the bladder, and eventually of the uterus.

The position of the uterus in the abdominal cavity should now be noted. The walls of the organ should be carefully palpated to see whether they contain a tumor, whether they are hypertrophied, and also to determine their consistency. Prolapse of the uterus should be differentiated from a polypoid myoma and from inversion.

Much may be done in the way of prevention of prolapse. A too early getting up after labor, thereby permitting a heavy uterus with lax ligaments to rest upon a distended vagina, should not be allowed. The formation of a cystocele, occurring as a result of an over-distended bladder should be prevented by the use of the catheter. If the perineum has been ruptured during labor, it should be repaired immediately. Lying upon the back constantly should not be allowed, as a condition favorable to retroversion is thereby maintained, but change of position, Fritsch thinks, should be insisted upon. Any backward displacement of the uterus should be corrected at an early date. If the vagina is found in a relaxed condition, astringent injections are called for, or the astringent can be introduced upon pieces of cotton. Violent exercise after leaving the bed should be forbidden, and care should be taken to have a regular movement from the bowels daily.

In beginning as well as in advanced, prolapse support may be given to the uterus by means of pessaries. Ring pessaries have been much used for this purpose; they are made of hard or soft rubber. The last-named variety appears to be the best. The disadvantage of this form of pessary is that the vagina becomes very much stretched by its use, and a larger size is needed every few months. The Hodge or Albert Smith pessary may be used, and sometimes the instrument gives much relief. Very many other kinds of pessaries have been used, but treatment of prolapse by this means is gradually giving way to operative treatment, which promises more permanent relief, and is attended with very little danger. Packing the vagina with cotton will sometimes keep a prolapse back, and has this advantage over support by a ring pessary that the vagina is not so much distended. A T bandage is worn in such cases. Professor F. Von Preuschen has quite lately reported three cures of prolapsus uteri treated by Brandt's gymnastic method. This consists in first pushing the uterus well up into a position of anteversion, when an assistant holds the uterus anteverted by means of a finger in the vagina, and the operator seizes it with the appendages and pushes them toward the umbilicus; this is repeated three times, the assistant seeing that the uterus does not become retroverted. Next, the knees of the patient are brought close together, and she is instructed to resist the force used to separate them; when they are thus separated, she is again told to resist the force used to bring them together; after this the sacral and lumbar regions receive a certain amount of tapping executed with the hand. The recorder of the cases thinks that the action of the adductors causes the levator ani to contract, and that this is most important; the whole muscular floor of the pelvis is, however, made in this way to contract. The following are the three cases in brief:

1. Woman, aged twenty-nine, with complete prolapse. Treatment began on April 18th, and lasted till June 2d, when she was pronounced well. The uterus remained in position after the first manipulation.

2. The external os was seen surrounded by the vagina. First treatment April 20th, ended July 1st, when the uterus was found to be in very good position.

3. Woman, seventy-one years old. Total prolapse. Treatment began on June 5th, and the patient remained till July 10th. The uterus remained in place after the first treatment.

These few cases reported appear to have had a most successful termination.

The whole uterus has been removed for prolapse a number of times. Saenger, Winiwarter, Martin, Leopold, and Thomas, have each done it. Martin lost his case through septic infection, but the other cases recovered.

The abdomen has been opened and the uterus drawn up and stitched to the abdominal walls. This is not infrequently done when the abdomen is opened for the removal of tumors, etc., but, as an operation for prolapse, it has not yet become very popular.

A ruptured perineum should be repaired by some one of the many plastic operations recommended.

Lacerations of the cervix should be attended to, and if there is much hypertrophy of this part of the uterus it should be amputated. For this purpose the cold-wire écraseur, the galvano-cautery, and the knife have been used. The first two methods leave a raw surface, which has to heal by granulation, and the os is in danger of closure. With the knife two wedge-like pieces are removed, one from each lip. A rubber ring or piece of rubber tubing is placed around the cervix to prevent hemorrhage; the cervix is split into an anterior and posterior lip. Each lip is then amputated separately, the flaps are brought together by wire suture, the vaginal and cervical mucous membranes coming together. Particular attention should be paid to the relation which the bladder and posterior vaginal fold bear to the hypertrophied cervix. The bladder, as well as Douglas's pouch, have been opened by this operation without bad results, though, of course, it is an accident to be avoided.

The Alexander-Adams operation for shortening the round ligaments of the uterus, and so bringing the organ into place, has found much favor lately.

The other operations aim at narrowing the vagina, arching it forward, and strengthening the recto-vaginal septum. Stenosis of the vagina has been produced in many ways by the use of nitric acid, chloride of zinc, and the actual cautery. Strips of mucous membrane have been removed from either the anterior or the posterior surface of the vagina, and the denuded surfaces brought together. The vagina is to be carefully washed out with a solution of carbolic acid or corrosive sublimate; then the line of operation is mapped out on the vaginal wall, and the mucous membrane is removed, the denuded surfaces being united by means of silk and catgut sutures, some deep, others superficial. They should all be introduced before any are tied, and are to be allowed to remain in place for from twelve to fifteen days. Hegar's operation is probably the most popular. Winkle has delivered women, after this operation had been done, without injury to the vagina.

Anterior or posterior colporrhaphy, together with amputation of the cervix, can be performed at one and the same time.

George Haven.

VESICO-VAGINAL FISTULÆ. A fistula is an abnormal communication through the tissues between two organs or passages, or between an organ or passage and the exterior of the body. The course of the communication may be either direct or tortuous. A vesico-vaginal fistula is such a communication between the bladder and vagina by means of which the urine constantly or spasmodically makes its escape.

These urinary fistulæ are classified according to their location as follows: I. Vesico-vaginal fistula (proper). This is situated in the vesico-vaginal wall and involves only that tissue. II. Vesico-utero-vaginal fistula. This comprises cases in which the tear reaches up to, or dissects off the vesico-vaginal tissue from the uterus, and necessitates the passage of the suture through uterine tissue in the repair. III. Vesico-uterine fistula. In these cases the vaginal wall is intact, the bladder communicating with the uterus and the urine thus finding its way through the os into the vagina. IV. Urethro-vaginal fistula. This is applied to cases in which an opening exists in the base of the urethra, through which urine escapes into the vagina. But this can only occur during the act of micturition. V. Uretero-vaginal fistula. This is the rarest form of fistula. It is the result of an extensive tear or loss of tissue by means of which the ureter is involved. Dr. Emmet claims that this lesion is more commonly the result of a pelvic abscess. During the inflammatory process the ureter becomes occluded by pressure, perforation ensues, and the urine finds its way into the vagina.

The most common location of a vesico-vaginal fistula is in the median line and directly behind the symphysis pubis. The usual form is oval, linear angular, or round. The most common is the oval, due, as Dr. Agnew explains, to the superior contractile power of the longitudinal over the circular muscular tissue of the vagina. These fistulæ vary in size from an opening so small that it is found with great difficulty and admits only the smallest probe, to those that involve the whole of the anterior vaginal wall, with entire base of bladder and the urethra. One illustration of the latter has come under my own observation and care. In this case there was no trace of urethral tissue whatever. The entire base of the bladder was wanting, and stretching across the common cavity behind the symphysis, and springing from and continuous with the tissue of the recto-vaginal septum, was a strong cicatricial band which reached from side to side of the pelvis, leaving only sufficient room for two fingers to pass with difficulty between it and the symphysis. Through this small opening the inflamed and sensitive fundus of the bladder frequently prolapsed. Such cicatricial bands, of greater or less density and resistance, and reaching across the vagina in the most diversified directions, are a common complication in cases of fistula.

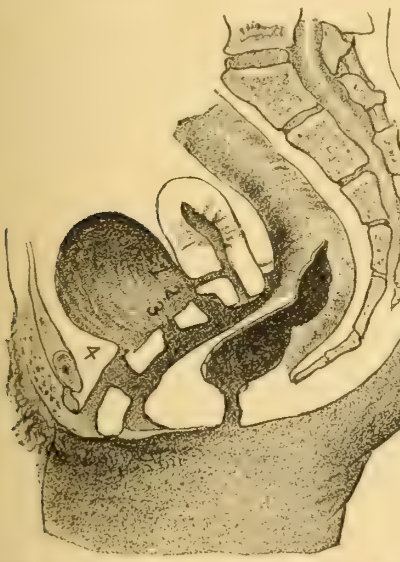

FIG. 5100.—Location of Fistulæ. 1, Utero-vaginal fistula; 2, vesico-utero-vaginal fistula; 3, vesico-vaginal fistula; 4, urethro-vaginal fistula.

Etiology.—The most common cause of urinary fistula is injury due to parturition. If the delivery be premature and rapid, especially when attended with undue rigidity of the soft parts, laceration of the cervix uteri is apt to occur. Especially is this the case in primipara of advanced age, and in cases in which morbid changes have occurred in this tissue. When sufficiently extensive this laceration results in a permanent fistula. The vesico-utero-vaginal and the vesico-uterine are the varieties most often produced in this way. The tear, beginning in a rigid os, extends out upon the vagina or up the cervix to the vesico-cervical junction. In the process of repair this may all heal, with the exception of an opening at the junction of the vagina with the cervix. Or all the tissues below may heal, leaving an opening at the upper angle of the tear—a vesico-uterine fistula.

It is universally accepted now, however, that the majority of fistulæ are caused by the sloughing away of tissue due to severe and prolonged pressure of the presenting part. So long as the pressure is intermittent and not too long sustained at any one time no harm is done; but when impaction occurs and the pressure becomes continuous, circulation is obstructed and the vitality of the soft tissue thus compressed is destroyed. Necrosis occurs, the slough separates, and the urine makes its escape. According to Agnew, over ninety per cent. of vesico-vaginal fistulæ are thus produced, while in Emmet's experience ninety-five per cent. of his cases were the result of prolonged and difficult labor.

When the fistula is produced by laceration the urine makes its escape at once and the condition is immediately suspected. But in cases of protracted labor time is required for the slough to separate, and the urine may not escape for several days. The average time is ten days, but it may occur in four or five and may be delayed for a month. One case that came under my care, when interne in the New York Woman's Hospital, gave a history of retention of urine, following confinement, till the ninth day, when suddenly her bladder burst and a flood of urine was discharged through the vagina. The cicatricial bands, however, which upon examination obscured the fistula, indicated a process of sloughing, and the separation of the necrotic tissue was to her the "bursting of her bladder." An interesting feature of this case might be mentioned here. The fistula was a vesico-utero-vaginal one, rather extensive, and in closing the wound the right ureter was involved in one of the stitches and became obstructed. This was indicated by sharp colicky pain, shooting along the course of the ureter on the right side and reaching to the kidney, attended about every three hours with a sharp spasm of pain and a gush of urine through the catheter that was in the urethra. When this was reported to the operator he refused to interfere with his stitches, maintaining that if the urine had found its way once into the bladder it could do so again, and would continue to do so till a permanent escape was thus established. His prediction proved true and the operation a perfect success.

Ill-adjusted, displaced, and neglected pessaries have been known to ulcerate through the vaginal wall and produce fistula; vesical calculi likewise may ulcerate through into the vagina, leaving a fistulous opening. Urinary fistulæ are also produced by firearms, by rough manipulation of sound or catheter in the bladder, by accidental puncture during operations on surrounding tissue, as in the operation for atresia vaginæ or amputation of cervix uteri in malignant disease, etc. Contrary to former teaching, malignant disease of the uterus in itself almost never produces a vesical fistula. The essential tissue of the bladder is so highly organized, so well nourished, that it is enabled to resist the encroachments of such morbid action. As has been said, however, fistulæ are not infrequently produced in the course of operations for the relief of such troubles.

Occasionally cases of congenital fistula present themselves, but they are rare. The same methods of relief apply to them as to other cases; but at an early age the parts are usually too small to permit of successful operation.

Symptoms.—In cases where the bladder is punctured by an incised wound, the fact is at once made known by an immediate and involuntary escape of urine through the puncture. The same phenomenon indicates the presence of a fistula caused by laceration, due to too rapid delivery, or by ulceration due to pressure of pessary, calculus, or any foreign body in the vagina. This escape of urine may be continuous from the date of its first appearance or may be interrupted. But as the vast majority of fistulæ are due to prolonged and difficult labor, the usual symptoms are those that follow such an experience. The bruised and sloughing tissues are a warning of the more serious condition to follow. But the actual extent of the injury cannot be known till the slough separates and the urine escapes by the fistulous opening thus established. This may occur on the third day, and may be delayed till the third week. From this time on the urine may flow constantly, or may be retained for several hours, dependent upon the position of the patient and the nature and seat of the fistula. If the fistula is high in the septum, the bladder will have retentive power till filled up to that point; and when the patient is in an erect posture there will be no involuntary escape of urine if the bladder is evacuated frequently enough to prevent the overflow. Sometimes a fold of the vagina, the pressure of the uterus, or the approximation of the edges of the fistula, especially in fissure-like openings, may afford retention for hours. In uretero-vaginal fistula, when only one ureter is involved, there may exist the unusual condition of a constant dribbling of urine from the vagina and occasional normal micturition.

Unless the woman devotes almost her entire time and efforts to personal cleanliness, the mucous and cutaneous surfaces over which the urine flows soon become inflamed and excoriated. The vulva, the thighs, and the nates, being kept constantly wet with this irritating excretion, become red, swollen, and abraded. Frequently they are the seat of vesicles and pustules, and even occasionally of deep ulcerations and abscesses. Such abrasions within the vagina soon become coated with a calcareous or phosphatic deposit, causing the greatest suffering.

When there has been an extensive loss of tissue the base of the bladder may become inverted through the opening, suffer the same abrasion, and become coated with the same deposit, rendering it exquisitely sensitive. Otherwise the size of the fistula makes little difference with the discomfort of the patient. Women are as constantly wet when the opening is not larger than a pin's head as when large enough to admit one or two fingers, the small opening, as Dr. Emmet explains, acting like the spigot in a barrel. A disagreeable urinous odor is constantly emitted from her person, which excludes her from society and forbids her participation in the ordinary pleasures and duties of life. Dieffenbach gives a sad picture of many of these unfortunate women of his time, shunned by their friends, disgusted with themselves, and dragging out a most pitiable and miserable existence.

Diagnosis.—When the symptoms above described exist, the probabilities are that a urinary fistula will be discovered. Sometimes, however, a chronic cystitis will result in paralysis of the bladder and constant dribbling of urine from the urethra, producing all the disagreeable symptoms of a fistula. If the fistula is large, a digital examination will readily detect the lesion without the use of speculum and probe; but pinhole openings are sometimes most difficult to discover, while in long-standing cases of extensive lesions, with abrasions and cicatricial bands, the relation of the parts is only discovered by careful and painstaking investigation. When the opening is very minute, the whole field of the vagina must be gone over carefully with tenaculum and probe. The folds of the vagina are smoothed out, the probe gently insinuated into every suspicious fold or fissure.

Should this fail to reveal the fistula, resort can be had to injecting milk into the bladder, or water stained with indigo or carmine. The bladder is slightly distended with the chosen fluid, while the septum is carefully watched for its appearance upon the vaginal wall. Bozeman has devised an ingenious test for cases in which the previous methods are contra-indicated by irritability of the bladder. The test is based upon the fact that urine instantly passes through linen, while secretions of the vagina do not. The suspected location of the fistula is carefully dried with absorbent cotton, a piece of thin linen is spread smoothly upon it, and carefully watched for the point of moisture to appear.

Prognosis.—In artificial fistula, made for the relief of calculus or obstinate cystitis, it is a well-known fact that it is with difficulty that the fistula can be kept open long enough to effect a cure. Not until Dr. Emmet devised his method of "working the button-hole" was this difficulty obviated. In these cases the fistula is a simple slit or fissure, the edges of which fall naturally together when the speculum is removed. We may, therefore, infer that where the lesion consists of a laceration in the vesico-vaginal septum, due to rapid labor or accidental puncture, unless it be so situated that the natural strain of the parts tends to keep the lips of the wound apart, under proper attention to cleanliness and frequent emptying of the bladder, spontaneous recovery may be hoped for. Even when a slough has occurred, spontaneous recovery has taken place in a limited number of cases. In the majority of cases, however, the lesion becomes permanent and requires surgical interference for its relief.

"Prior to the application of the metallic suture by J. Marion Sims and a proper mode of exploration furnished by his speculum, any attempt for the relief of the injuries under consideration was uncertain in result, and the operation regarded as an opprobrium by the profession." To fully appreciate the significance of these words of Dr. Emmet, and the credit due to Sims, it may be interesting and profitable in this connection to look into the history of the treatment of the lesion under consideration.

History.—With Henri de Roonhuysen—a Dutch obstetrician of Amsterdam, 1663—rests the honor of being the first to devise, employ, and describe the operation for relief of vesico-vaginal fistula. The description he gives is so unique and interesting, and so rarely to be found, that I give it in full. This is from a French translation of the original by Herrgott of Strassburg. The operation is done in the following manner: The patient is placed upon her back on a table in a good light; the upper part of the body is covered, the lower part fixed with bands as in the operation for cystotomy. This done, the vagina is dilated by a speculum as large as the circumstances will permit. The vaginal mucous membrane along the border of the tear, where it is in contact with the vesical membrane, must be denuded, but the bladder itself must be touched as little as possible, for by the kindly act of nature the vagina is united by inflammation to the borders of the tear in the bladder in such a way that when only as little a portion as necessary has been detached, it is wont to heal perfectly. This freshening of the edges can be done by means of a little sharp pinch of the scissors or bistouri, or any other instrument the surgeon is in the habit of using. I find it is accomplished quite well by a slight sharp pinch of the scissors, but they ought to be as sharp as possible in order that they may not produce contusion, but freshen a little the edges of the tear to make them red or bleeding, so that they may unite immediately and contract adhesions to each other. The retention need not always be accomplished with gold or silver pins, as is done in harelip, but with pins made from the strong quills of the swan, sharpened and pointed. These are preferable not only by reason of their flexibility, but by the fact that they do not cause compression of the surrounding parts if one takes the precaution to guard them with waxed silk. For when the pins are applied they adapt themselves by virtue of their elasticity.

The parts must then be anointed with a cicatrizing salve (of which he gives the formula), and upon the wound should be placed two or three flat pledgets saturated with oil or warm balsam, and the vagina filled with pieces of sponge saturated with oil, for the purpose of making a little pressure upon the wound and sustain the dressing. All this should be steadied with some compresses and supported by a T-bandage, which should remain in place three or four days. The bandage and compress are removed when the patient wants to urinate, but she ought to do it with caution. The patient should remain constantly in bed, lying upon her back, the hips slightly elevated, till healing is accomplished.

Roonhuysen does not describe cases operated upon by himself, nor does he state how many times he practised it; but a Swiss surgeon, J. Fatio, 1752, records two successes by Roonhuysen's method. Naegele claimed that this procedure of Roonhuysen was simply impossible, basing his objections upon the quill pin, but he nowhere claims to have tried it. Kilian made similar objection to the operation. But Herrgott has experimented with quill sutures in tissue similar to that of the vagina, and finds them entirely practicable. Moreover, the minute and careful description of all the details of the procedure bears evidence in itself of being a genuine account of what had actually been done.

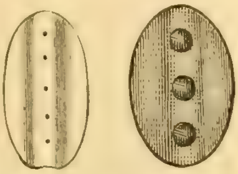

Fig. 5101.—The Lead Button.

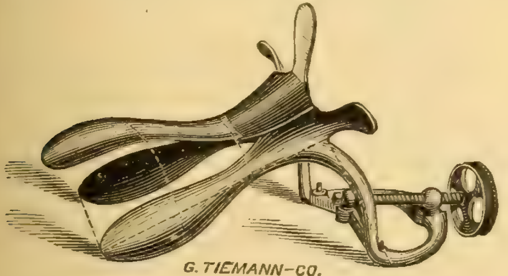
In this simple description of Roonhuysen's we find all the principles and methods of treatment necessary to deal successfully with fistulæ. He used the speculum to thoroughly expose the parts, vivified the edges of the fistula with knife or scissors, avoided the bladder membrane in denuding, and fastened the edges with a suture. What have we added to this more than to modify the suture and adjust a self-retaining catheter?

The method, however, was not established, either by him or any of his immediate followers, as a recognized procedure in surgical practice, and was forgotten. No progress in dealing with fistula was made during the eighteenth century, except the use of the catheter, by Vorlten, 1720, and the introduction of silk interrupted sutures. Cauterization of the edges with hot iron and nitrate of silver was used, but with only limited success. In the beginning of this century Naegele, 1809, renewed interest in this lesion and its repair. He devised and employed four methods of operation, but failed to obtain any success. Professor Ehrman, 1826, operated in two cases by simple suture after freshening the edges, and obtained complete success in one after repeated cauterizations.



G. TIEMANN-CO.
Fig. 5102.—The Bozeman Speculum.

Gosset, of London, 1834, reported a successful case operated upon by him, in which he used uninterrupted sutures of silver gilt, or gilded silver wire, fastened by twisting. Jobert de Lamballe, the same year, in France, introduced the method of transplanting tissue from the labia, the buttocks, or thigh, and fastening it to the denuded edges of the fistula. This did not prove satisfactory in its results, and he adopted the interrupted suture with the additional procedure of incising the tissues at certain points in the vagina—cystoplastie par glissement—to relieve tension upon the sutures and allow the edges to rest in contact.

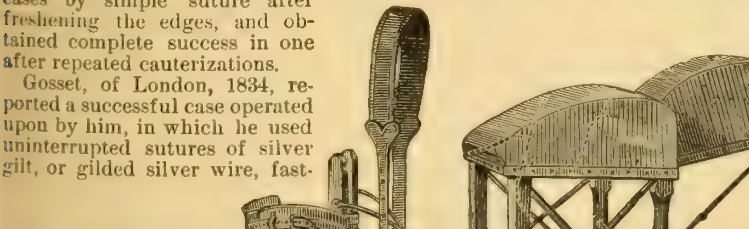


Fig. 5103.—The Bozeman Chair.

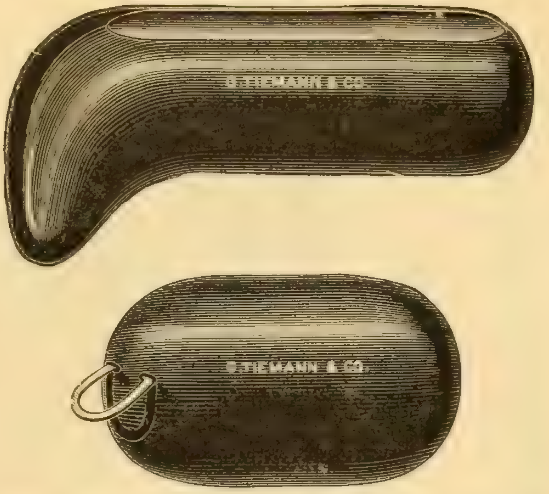
Then Dieffenbach, 1845, gave his experience to the profession. He says: "I have operated upon one woman eighteen times without success. I have closed the entire cavities of these unfortunate women gathered from all countries. I have lived in the midst of them, and I have realized only a small number of successes." He claimed to have cured by the suture only one fistula of any considerable size, but a great number of small ones by the actual cautery.



G. TIEMANN & CO.
G. TIEMANN & CO.
Fig. 5104.—The Bozeman Hard-rubber Dilator, Pistol-shape and Oval.

Wurtzen, of Bonn, who after Dieffenbach was for a long time the only one who operated upon fistulæ, failed to cure in one case after thirty-three operations. According to the statistics of Simon, Wurtzen, up to 1842, cured only 4 women out of 18. From 1842 to 1852 he cured 7 out of 17, or 11 successes in 35 cases.

Gustave Simon, 1854, published a critical review of the operation of Jobert in which he presented his own method of operating, and reported six cases in which he had obtained perfect success in four, and partial success in the other two.

In our own country, Hayward, of Boston, was the first to report a cure, May 10, 1839, achieved by him in a case of fistula of fifteen years' standing, which had resisted treatment by cauterization and catheter. He operated with the patient in the lithotomy position, the vagina opened by means of retractors, and the anterior vaginal wall pressed down by a bougie in the bladder. The edges were denuded, the surfaces coaptated by interrupted silk sutures, a catheter fastened into the bladder, and the patient put to bed upon her right side. Upon the sixth day firm adhesion had taken place and the stitches were removed. He says: "I had never seen the operation done till I did it myself, nor could I find any description of the mode which others had adopted that was sufficiently clear and explicit to be of much service." In 1851 he reported a series of 20 operations on 9 different patients, with 3 perfect successes, 4 great relief, 2 no benefit. Of these 5 had 1 operation, 2 had 2, 1 had 5, and 1 had 6.

In 1847 Pancoast, of Philadelphia, reported two cures by a method called the "gusset suture." The peculiar feature of this consisted in splitting one edge of the fistula and paring the other to a wedge shape. The latter was then engaged into the former and held by sutures. The same year, 1847, Mettauer, of Virginia, reported a successful case of fistula treated by him with leaden sutures after freshening the edges. He also used the catheter. So simple seemed the process of cure, and so pronounced his success, that he did not hesitate to declare all fistulæ in the realm of relief.

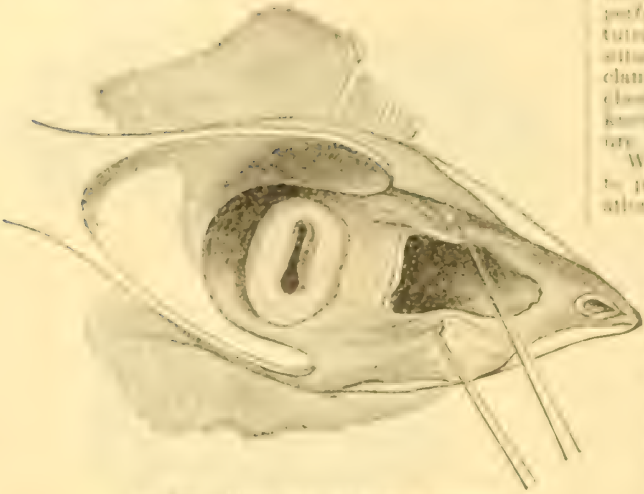


FIG. 5105.—Fistula as shown by Sims' Speculum.

From this brief historical sketch it becomes apparent how perfectly at sea the profession was even as late as the middle of the present century, regarding any well-established procedure, or faith in the successful application of any of the devices used. Here and there, occasionally, an operator met with success, and the achievement was heralded as a great triumph. But no two adopted exactly the same method, and the success was ascribed more to good luck than the proper application of any particular surgical method. It was left for the genius, the careful observation, the untiring energy and enthusiasm of one of our own countrymen, J. Marion Sims, to grasp all the essential principles, to work out to complete success, and give to the profession what is recognized the world over as a thoroughly reliable method of dealing with urinary fistula. The more credit is due him as he worked independently of others and without any adequate knowledge of what had been accomplished by them. Yet, as Dr. Emmet says: "were we to accept that Dr. Sims was as familiar as we are at the present time with what had been accomplished before his day, it should not lessen the credit due to him. What had been done fell on barren soil, its fruit was not appreciated and was destined to be forgotten. From Dr. Sims' hands the operation was accepted by the profession. It was immediately put into successful practice, and to the present day it has not been materially modified, for the better, either in its principles or in the mode of execution." His first article was published in the American Journal of the Medical Sciences, 1852. The essential features of the procedure, as there set forth by him, were, first, a means by which the vagina could be thoroughly exposed and the fistula brought into view, viz., the knee-chest position and the duck-bill speculum; second, a suture which could be left in place long enough to secure healing without exciting inflammation or ulceration, viz., silver wire secured by perforated shot; third, a method of draining the bladder during convalescence—Sims' self-retaining catheter. During the next five years he modified somewhat the details of these procedures and set them forth in an address before the New York Academy of Medicine, 1857, "Silver Sutures in Surgery." In the operation as then described and which he regarded as perfect in all its details, he substituted the simple interrupted silver suture, secured by twisting, for the clamp-suture, and instead of the knee-chest position, employed what is known universally as the Sims posture.

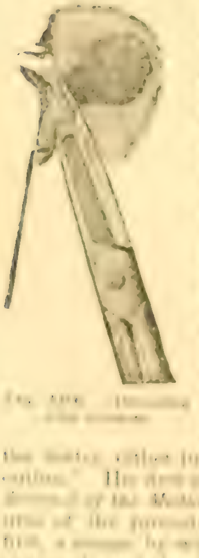

FIG. 5106.—Denuding with Scissors.

While Sims was thus working out to perfection the details of his operation, Gustave Simon, of Darmstadt, Germany, was also employing his mechanical skill and ingenuity in endeavors to relieve the same distressing affliction. The results of his labors, and the details of his operation, were given to the profession in 1862, although he had previously published an article on the subject in 1854. He placed the patient in an exaggerated lithotomy position, exposed the fistula by a duck-bill speculum of his own device, and by means of lateral retractors, vivified the edges with a knife, regardless of encroachments upon the bladder membrane, and used silk sutures in uniting the edges. When much strain was expected, he employed a row of deep sutures far from the edge to hold the parts, and a row of superficial sutures to secure exact approximation of the edges. He allowed his patients to sit up and pass urine naturally when possible. Simon also devised and practised what he called Kolpokleisis, in cases in which the fistula itself could not be closed. This consisted in completely occluding the vagina by denuding a surface on the anterior and posterior wall of the vagina below the fistula, and uniting them by suture. This made a common receptacle for the urine and menstrual blood.

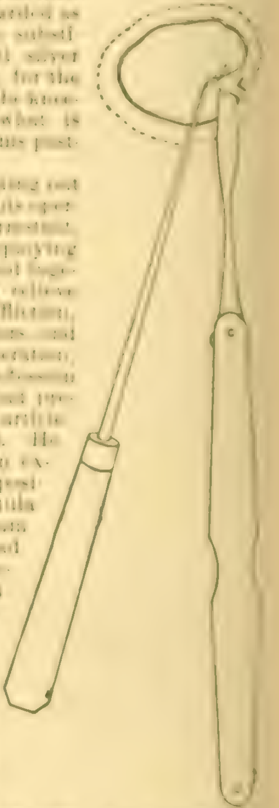

FIG. 5107.—Denuding with Knife.

Intimately associated with the operation for repair of fistula, both in this country and abroad, is the name of Bozeman. He is a strong advocate of long and complete preparatory treatment and the use of the button suture. The latter consists of a disk of sheet lead nicely cut and moulded to fit the tissues in each individual case. This is perforated with a row of holes along the median line, through which the silver sutures are drawn and made fast by perforated shot (Fig. 5101). This, it is claimed, acts like a splint, and so favors healing by preventing motion. It has the disadvantage, however, of concealing the wound, preventing the nice adjustment of the edges and the tightening or loosening of each individual stitch which is afforded by twisting the wire. He employs a peculiar speculum invented by himself and a contrivance for sustaining the patient in the knee-chest posture when under ether (Figs. 5102 and 5103).

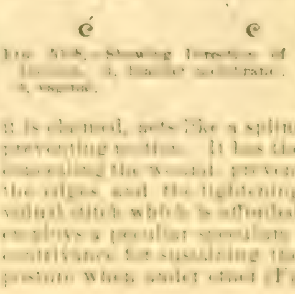

FIG. 5108.—Showing Inversion of Edges. a, Bladder membrane; b, vagina.

His method yields most favorable results in his own hands, but is too complicated for the general practitioner.

Dr. Bozeman is a vigorous opponent of the operation of Kolpokleisis as practised by Simon. He claims that in many cases where this was resorted to by Simon, a sufficiently long and persistent course of preparatory treatment would have enabled the patients to be relieved with entire restoration of bladder and marital functions. Kolpokleisis, even in cases that resist all other efforts at relief, is only a delusion. It may keep the patient dry, and thus afford relief for a short time; but unfortunate consequences always attend the retention of urine in a pouch thus formed when complete drainage is not secured. The urine decomposes, calculi form, and a cystitis may be established that, sooner or later, leads to disease of the kidney, uræmia, and death. Dr. Emmet insists that Kolpokleisis should never be resorted to under any circumstances.

The man that has done the most to popularize operation for fistula in this country, while claiming no originality in the matter, is Dr. Emmet.

Frequency of Fistula.—No statistics can be given, showing the frequency of this accident. There is no hesitancy in saying that it is a rare condition, and, if the experience of New York gynecologists is an index of experience throughout the country and the world, it is becoming more and more infrequent. The Woman's Hospital, in New York City, was established primarily for the express purpose of relieving fistulæ, and its early history bears record of few cases of a different nature. During the first five or six years of its existence it was customary to have two or three operations each week for relief of fistulæ. At the present time scarcely that number can be seen there in a year.

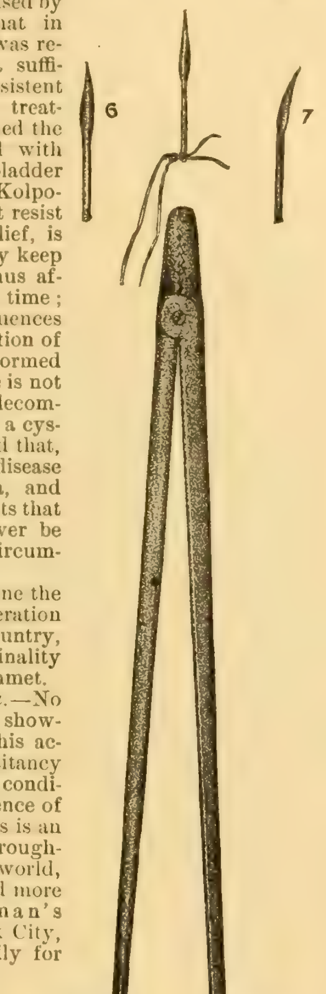

Fig. 5109.—Needles and Needle-holder.

This change is due to two causes: First, the operation has become so popularized that when such accident does occur, the local physician repairs the injury; second, the prompt application of forceps in cases of difficult labor prevents its occurrence. Whatever abuses and injuries may attend the too frequent and too early use of forceps in parturition, all authorities are now agreed that their timely use is most efficient in preventing fistulæ. "Authors are disposed to attribute the accident of vesico-vaginal fistula in many cases to the awkward use of obstetric forceps; but from careful analysis of these cases, and my own experience, I am well satisfied that for one case thus produced their judicious application has prevented it fifty times" (Sims). "I do not hesitate to state that I have never met with a case of vesico-vaginal fistula which, without doubt, could be shown to have resulted from instrumental delivery" (Emmet).

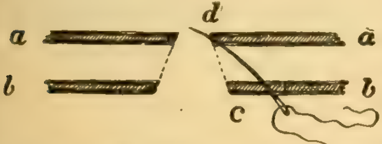

Fig. 5110.—Direction of Needle. *a d*, Bladder membrane; *c b*, vagina.

Treatment.—Methods of Cure. Spontaneous Cure. Small fistulæ will frequently close without any interference, through the process of healing and granulation. The smaller the fistula the greater the probability of such an occurrence. This process of nature can be encouraged and hastened by proper attention to cleanliness. The constant drainage of the bladder, too, by self-retaining catheter, assists greatly this spontaneous cure. Any procedure that maintains a constant healthy, granulating process along the edge of the fistula tends to recovery. Corradi cites a case of his, recorded by Jenks, which for a year had resisted all methods of treatment, even Sims' operation. He thereupon had a gold button with double facets made to fit the fistula. The button was inserted so that one facet was in the bladder, the other in the vagina. Micturition was immediately established, and not a single drop of urine passed any longer by the vagina. For five years the woman wore this button without experiencing any inconvenience. Then by accident the button dropped out, and the urine continued to pass entirely by the urethra. A few days afterward Corradi examined the patient, but found no fistula. In this case the stimulus of the button had encouraged granulation till it had reached up over the head of the facet that was in the bladder, while the button was sloughing out below.

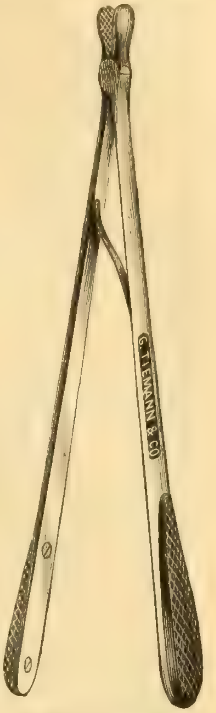

Fig. 5111.—Emmet's Needle-holder.

Fig. 5112.—Sims' Fork.

Caustics.—For many years caustics were the chief reliance in the cure of fistulæ. As late as 1839, Dupuytren declared that sutures were of no avail against the injurious influence of the urine on the wound, and nothing but the actual cautery was sufficient to excite the necessary degree of action in the edges of the fistula to produce a full granulation. All the caustic acids, caustic potash, nitrate of silver, and the actual cautery were employed. In cases of extremely small fistulæ the cautery will frequently effect a cure. Nitrate of silver is the best application. It is also frequently resorted to with success to complete the cure after suture, when an opening has been left in the angle, or points along the line of union have failed to unite. In such cases frequent application should be made and continued till strong, healthy granulation has been produced. After that cauterize less frequently; allow the granulations to accomplish what they can before burning them again.

Preparatory Treatment.—It is important that the general health of the patient should be in as good condition as may be. But one need not wait too long for this. The local condition of the parts is still more important. Before operating, the edges of the fistula and surrounding parts must be put into as healthy condition as it is possible to get them. Sitz-baths, hot-water douches, and the most scrupulous methods of personal cleanliness should be employed. All incrustations of urinary salts, wherever found, are to be gently removed by streams of warm water, a cotton swab, or picked off with the dressing forceps. The excoriated surface beneath is then brushed over with a solution of nitrate of silver. This must be persisted in two or three times a week, and in the meantime the parts kept thoroughly protected from the urine by an ointment. The most efficient ointment for this purpose is that given by Bartholow, under the head of "Hebra's Ointment": "Take of benzoic acid, finely levigated, one part; white wax, one part; paraffin, two parts; almond oil, two parts. Melt the wax and paraffin by heating with the oil, and stir the mixture briskly, along with the benzoic acid powder, in a warm mortar, until the mixture thickens." When required for use, a certain amount of it should be rubbed up with a little vaseline or glycerine. It should be used quite stiff, so that it may form a coating over the inflamed and delicate surfaces. With careful attention to cleanliness, and constant use of this ointment, I have kept patients with artificial fistulæ entirely free from all excoriations or irritation.

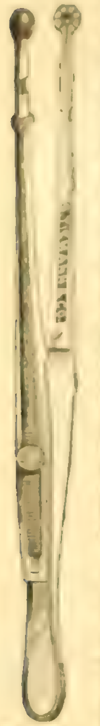

Fig. 5113.—[illegible]

All cicatricial bands stretching across the vagina, obstructing the view, narrowing the canal, or distorting the relations of the parts, must be thoroughly obliterated. This is accomplished by nicking or cutting them here and there along their course, and causing their absorption by pressure. When these constricting bands exist across the posterior wall, reaching up onto the sides of the vagina, they can be put upon the stretch by placing one or two fingers in the rectum and the thumb in the vagina. Then with a pair of blunt scissors in the right hand each band is snipped or cut superficially at several places, and the pressure of the thumb increased to tear the tissue still deeper. This avoids the hemorrhage that would be produced by the deep incisions of a knife. When the bands cannot be reached in this way, a speculum must be inserted and pressure made here and there with a depressor to bring the bands into view,—when the same process of snipping is repeated. To keep these bands on the stretch and stimulate absorption by pressure, a "Sims glass plug," or "Bozeman dilator" (Fig. 5114) is immediately inserted, and held in place by a layer of cotton and a T-bandage.

This plug or dilator can be procured of any size, and must be adapted to each individual case. It should be large enough to distend well the parts. Its presence occasions some distress, which may be relieved by anodynes. During the healing process the patient is kept in bed, and the plug held as constantly in place as the circumstances will permit. It should be removed at stated intervals to permit of antiseptic douches, and well smeared with carbolized vaseline before being reintroduced. At the expiration of ten days or two weeks, if the parts are not sufficiently pliable and the vagina roomy enough to permit the easy performance of the operation, the process is to be repeated.

If cicatricial bands do not exist, but the canal is narrowed through loss of tissue, and the edges of the fistula so drawn apart that they cannot be brought into apposition, longitudinal incisions, three or four in number, parallel to the long diameter of the fistula, should be made through the membrane of the vagina with a knife, and the dilator or plug inserted as described above. Sometimes this becomes a very painful and tedious process, but is absolutely essential to success.

Fig. 5114.—[illegible]

Sims' Operation.—The patient, properly dressed and protected by covering, is placed in Sims' posture. It is well to have two nurses and two assistants. One nurse holds the speculum and elevates the buttock; the other attends to the sponges. One assistant administers ether; one assists in the operation and does the sponging. The instruments required are: Sims' speculum, long-handled left and right curved scissors (Emmet's curved scissors are usually sufficient), a long-handled knife with narrow blade, two or three tenacula, needles and needle holder, counter-pressure hook and fork, twisted silk for carrying thread, No. 27 or 28 silver wire, twisting forceps, wire shield, sponge holders and sponges (see accompanying cuts).

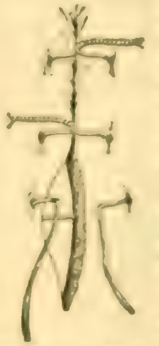

Fig. 5115.—Adjusting the wire.

The steps in the operation can be comprised under three heads: First, denuding or vivifying the edges of the fistula; second, introducing the sutures; third, adjusting the edges and fastening the sutures.

Denuding.—The line of union should be as nearly as possible in the long axis of the vagina; but more important still is it that the margins be drawn together in the line of least traction or resistance. The margin of the fistula is caught with a tenaculum at any selected point, and a strip of tissue removed with the scissors or knife.

It is a good plan to make this strip of tissue encircle the entire fistula without cutting or breaking it. Then you are sure of obtaining a perfectly clean surface. When the vesical mucous membrane is included in this denudation, there is apt to be troublesome hemorrhage. Sims therefore advised that this be carefully avoided; the incision taking the direction of the dotted lines as in Fig. 5108, *a* being the vesical membrane and *b* the vaginal. If the removal of one strip gives sufficiently wide surface to afford firm union, the wound is ready for the sutures.

Ordinarily, however, it is necessary to take off a second or third strip outside this, on the mucous membrane of the vagina, to get as broad a surface of union as may be.

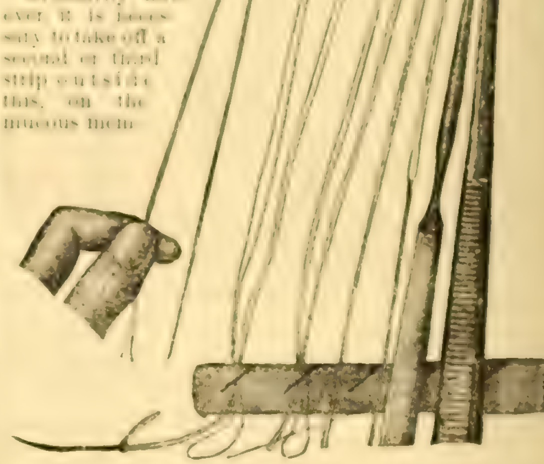

Fig. 5116.—Twisting the Wires. (Savage.)

At each end of the fistula the denudation must be made to terminate in an acute angle by extending the denudation out to a point on the vaginal membrane. This avoids all puckering of tissues when the sutures are tightened, and thus prevents the little orifices that otherwise are apt to result at either end of the line of union. Should any troublesome hæmorrhage occur, it can usually be controlled by hot sponges, torsion, pressure, or ligature. To exert pressure, Dr. Emmet recommends pushing the centre of a handkerchief, or any thin cloth, through the fistula, then packing cotton into the sac thus formed in the bladder till the mass is too large to be drawn through the opening. Now, by pulling on the corners of the handkerchief, any degree of pressure can be made. Another device of Dr. Emmet is to pass a suture from the vagina through the septum into the bladder, at some distance from the margin of the fistula, and out into the vagina again, thus surrounding the offending vessel, and ligating it temporarily in the tissues.

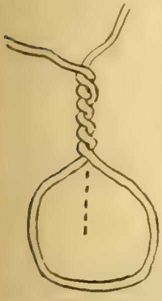

Fig. 5117.—Stitch before Shouldering. (Mundé.)

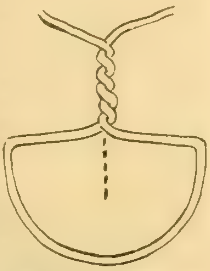

Fig. 5118.—Stitch after being Shouldered. (Mundé.)

Care must be taken in doing this to avoid ligating a ureter. If the mouth of the bleeding vessel can be caught, there is no positive objection to ligating with fine silk or catgut; but any foreign body between the lips of the wound is to be avoided if possible.

Introducing the Sutures.—The needle may be either straight or slightly curved, and from one-half to one inch in length. It is armed with a double carrying thread of fine silk about six inches long, into which the silver wire of the same length is hooked and made fast. The wire should be sharply bent over the thread and passed at that point with forceps, to make as slight a resisting point as possible in passing through the tissues.

It is well to begin suturing at the most distant angle of the fistula. Here the tissue is caught up with a tenaculum and the needle inserted at about one-fourth of an inch from the margin of the denudation, and directed through the tissues so that it will come out just at the edge of the bladder mucous membrane.

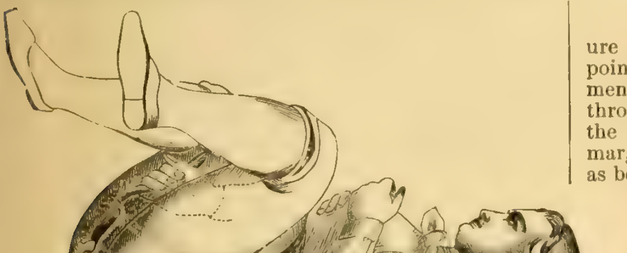

Fig. 5119.—Patient in Position. (Simon.)

Puncturing the vesical membrane causes hæmorrhage at the time, and may result in a permanent leak hole. As soon as the point at which the needle is to emerge is determined, counter-pressure is made just beyond with the blunt or counter-pressure hook. This facilitates the passage of the needle, and prevents straining of the tissues. The needle is thus pushed through as far as the grip of the needle-holder will allow. Then it is caught at the point and drawn through while the counter-pressure is still applied. The needle is then inserted at the point corresponding to its exit on the edge of the bladder membrane, on the opposite side of the fistula, and directed through the tissues till it makes its appearance through the vaginal membrane one-fourth of an inch from the margin of the fistula. The counter-pressure is applied as before. The needle, with carrying thread and silver wire, is now drawn through till the ends of the wire can be grasped on both sides. If the tissues are delicate and there is danger of tearing them, it is well to support the thread as it is drawn through with a Sims fork. But the wire must not be drawn into the tissues till the needle has been passed through both sides, and then it is to be slid through both sides at the same time. Otherwise it gets badly kinked. The ends of the wire are twisted together one or two turns, and held out of the way by the assistant. In this way the stitches are passed one after the other from one-fourth to three-eighths of an inch apart, and as evenly in all respects as it is possible to get them.

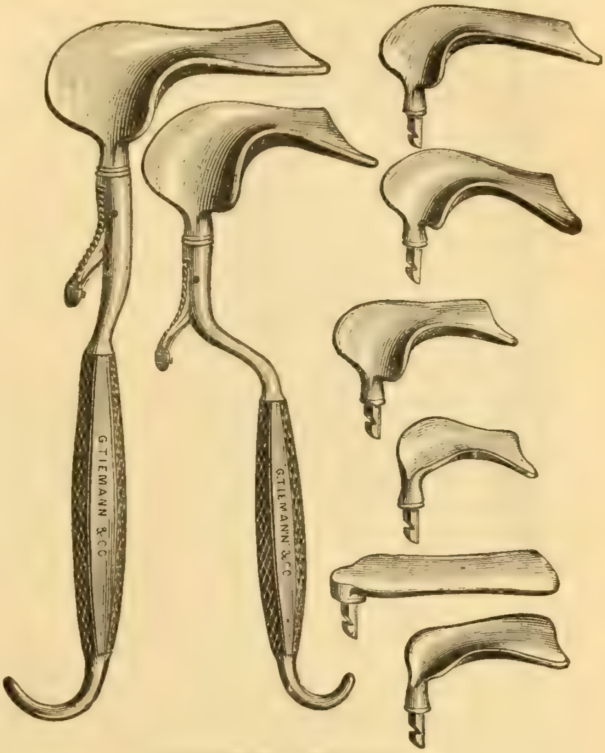

Fig. 5120.—Simon's Speculum.

Securing the Stitches.—Commencing again at the remoter angle of the fistula, both ends of the first wire are grasped firmly, two or three inches from the tissues, with the twisting-tongs, and sufficient tension made to draw the suture taut. With slight pressure of the tenaculum the wire of either side is now bent, near the tissues, at a sharp angle, till it meets the wire of the opposite side directly over the line of union that is to be formed. The shield is slid down the wire and firmly pressed against the tissue, while sufficient strain is put upon the wire, by pulling, to bring the edges of the wound into firm apposition. While this tension is still maintained, the wire is bent over the shield and twisted down to the tissue. The shield is now removed to see whether this suture holds the edges in close and even apposition. If not, the shield is reapplied and one or two more twists are given to the wire. Or if too tight and strangulation or cutting of the tissues threatens, the tension can be relaxed by giving the wire one or two turns in the opposite direction. And in this lies the advantage of securing silver wire by twisting rather than by clamp, button, or shot.

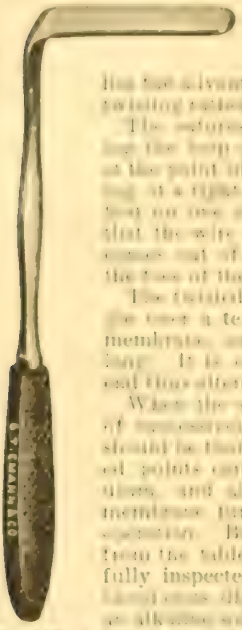

FIG. 5121.—Simon's Retractor.

The sutures are now shouldered by catching the loop of the stitch with a tenaculum at the point of exit from the tissue, and pulling at a right angle to the line of the fistula, first on one side and then on the other, so that the wire is bent at a right angle when it comes out of the tissue and lies flat across the face of the wound.

The twisted end is now bent at a right angle over a tenaculum, flat upon the vaginal membrane, and cut off about half an inch long. It is customary to turn the twisted end thus alternately one side and the other.

When the sutures have all been disposed of successively in this manner, the wound should be thoroughly inspected and all everted points carefully tucked in with a tenaculum, and all inverted points of mucous membrane turned out. This completes the operation. But before the patient is removed from the table the bladder should be carefully inspected by passing a catheter. Any blood-clots discovered must be dissolved by an alkaline solution and washed out; any active hæmorrhage controlled by hot water or ice-water injections.

The self-retaining catheter is now placed in position, and the patient put to bed with a narrow dish between her thighs to catch the urine. The catheter should be removed and thoroughly cleansed every night and morning, and a vaginal douche administered at least once a day. The bowels may be kept constipated till after the fifth day, or an evacuation obtained daily by Hunyadi water or other laxative. It was Dr. Sims' custom to keep the bowels quiet. The patient is kept upon her back, and pain is relieved by opium or morphine. The sutures may be removed upon the eighth, tenth, or twelfth day, according to the relative vitality of the patient, and the healing qualities of the tissues.

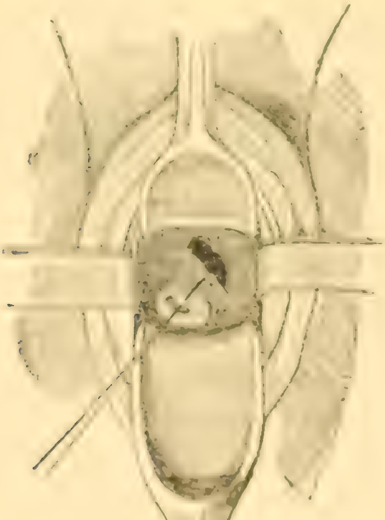

FIG. 5122.—Fistula as shown by Simon's Speculum.

Care must be exercised not to pull the wound apart in removing the sutures. Catch the twisted end with the twisting-tongs and straighten it up gently at a right angle with the surface. In doing this the loop of the suture will rotate in the tissues and bring a bright point of it into view, when it can be easily snipped off with scissors. The view is facilitated by making slight pressure on the tissues with the points of the scissors at the point of exit of suture. In drawing the suture out, force should be directed in such a way that the tissues are constantly pressed toward the line of union, and not dragged away from it.

Some cases require several operations to effect a cure, but slight points of non-union, either at the angles or along the line, may be made to heal by touching them frequently with the stick of nitrate of silver and by keeping the catheter in the bladder.

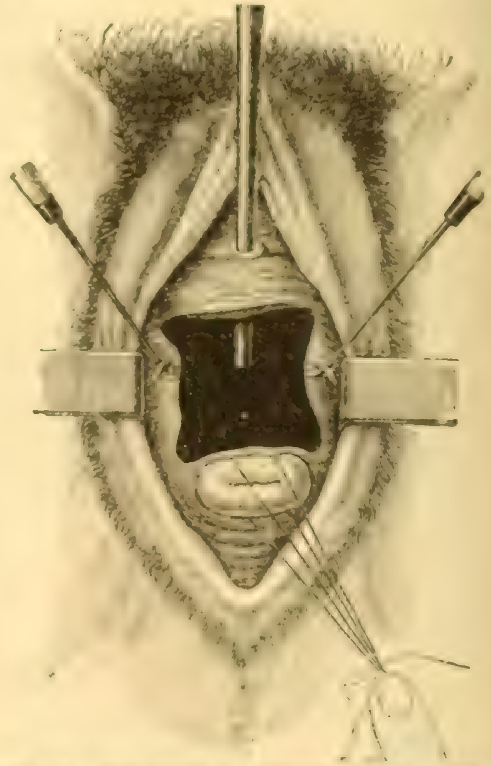

FIG. 5123.—Fistula shown with Retractors and Staff. (Simon.)

Simon's Operation.—It will not be necessary to describe so minutely Simon's operation, but simply to speak of the main points in which it differs from the Sims operation, and illustrate them by the accompanying cuts. Simon worked along the same lines of procedure that Roonhuysen described, and not only attained great success in his operations, but caused it to be adopted among his German confrères as the standard operation. The characteristic features of Simon's operation are these: First, he employs an exaggerated lithotomy position (patient on back, hips elevated). Second, instead of avoiding the vesical membrane, he intentionally incises it if the edges contain much cicatricial tissue. Third, he repudiates the superiority of silver wire, and uses silk. Fourth, he employs no stationary catheter, and allows the patient to void her urine if possible. Fifth, the bowels are kept in a relaxed state to avoid straining, diet is not restricted, and patient is not necessarily confined to bed.

Position of the Patient.—The breech-back (Steiss-Rückenlage) position is attained by elevating the hips and flexing the legs over the belly, so that the breech becomes the most projecting part. If the fistula is situated high in the vagina, the hips must be well elevated, and the thighs flexed as much as possible. The lower the fistula is situated in the vagina, the less the degree of elevation and flexure necessary. Whenever it is possible to expose the fistula well by traction upon the cervix, either by forceps or threads passed through, the speculum is dispensed with, and only side retractors are used, with a staff through the urethra to steady the parts. When this is not practicable he uses specula devised by himself. These consist of an anterior and posterior speculum, and two side retractors (Fig. 5120).

Vivifying the Edges.—The Simon method carries the incision deep enough to extirpate all cicatricial tissue, making a funnel-shaped excavation, and includes all the tissues down through the vesical mucous membrane. Simon prefers the knife.

Sutures.—When the fistula is small a single line of silk sutures is used. In the larger fistulæ every second or third stitch is made a sustaining suture, and is passed at considerable distance from the edge, thus including enough tissue to support the line of union and take the strain off the more superficial (uniting) sutures. This he called his double line of sutures. It is of very little importance whether the suture goes through the vesical membrane or not. But care must be taken to prevent the membrane being inverted and caught between the edges of the wound.

After-treatment.—The patient takes any position in bed that she desires. She passes urine normally whenever she feels the desire, either lying upon a bedpan, sitting up, or getting on the hands and knees. If urination is impossible without too much straining, the catheter is passed at proper intervals. A daily vaginal douche is given, and the bowels are kept open. Vesical tenesmus is relieved by sedatives. Silk sutures cannot be left as long in place as silver wire. They should be removed from the sixth to the eighth day.

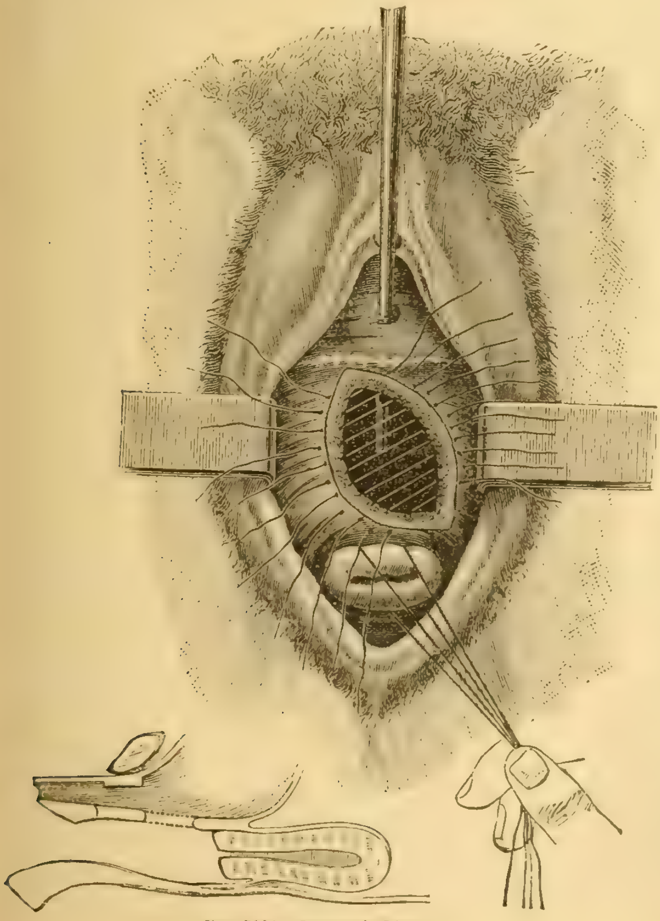

FIG. 5124.—Sutures in Place.

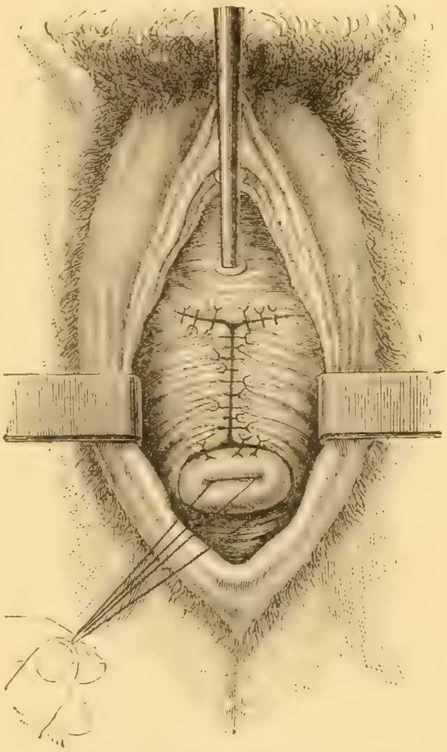

FIG. 5125. Lines of Sutures to close Fistula shown in Fig. 5124.

General Remarks.—The principles and methods established by these great teachers, Sims and Simon, can be followed successfully in all cases. Succeeding operators have modified many details, or combined into a successful procedure some of the features of each. Each operator follows his own fancy in regard to the needle or needle-holder which he shall use, and the material of which his ligatures shall be made. Chinese silk, silver wire, iron wire, silkworm gut, and chromicized catgut are used indifferently; but in large fistulæ, and those so situated that they cannot be reached easily to fasten the ligatures, silver wire is preferable.

There is no department of plastic surgery which gives so great scope for the ingenuity of the operator as that of fistulæ. Each case is a problem *per se*, and demands its own special and individual treatment. No case should be undertaken without careful study of all the factors that are involved in its successful treatment. Where one or more fistulæ exist near the neck of the bladder, there is apt to be stricture of the urethra, which must be relieved before any attempt is made to close the fistula.

In cases that involve loss of tissue at the lower portion of the vagina, extending to one or both rami, there may not be enough tissue between the fistula and bone for the passage of the sutures. In such cases the tissue can be dissected up from the bone to a sufficient extent to give holding ground for the sutures, or a flap may be dissected off the vagina above and brought around to cover the opening. Jobert was the most skilful operator in the use of flaps, which he procured from other portions of the vagina, from the labia, or even the buttocks and thighs.

In vesico-utero-vaginal fistulæ, where it is possible, only the anterior lip of the cervix uteri should be utilized to close the opening;

but in some cases it is found necessary to stitch the posterior lip to the anterior border of the fistula, thus turning the os uteri into the bladder. Menstruation then occurs through the bladder, and conception, as a rule, becomes impossible.

In uretero-vaginal fistula, Dr. Emmet boldly slits up the ureter till he reaches the fistulous opening, thus, as he phrases, reproducing the original lesion. The fistulous tract is then freshened and the entire wound closed by sutures as in trachelorrhaphy. Uretero-vaginal fistulæ are perhaps the most difficult to deal with. Landau recommends excising several pieces from the vesical and vaginal wall, thus producing a vesico-vaginal fistula into the upper angle of which the ureter opens. Then the fistula is to be closed by sutures which, at the upper angle, shall only include the vaginal membrane. If the urine is successful in forcing its way into the bladder in spite of the partial constriction of the ureter which may occur from the stitches, it will continue to do so. There is no danger of occlusion by granulation, for the flow through the ureter is constant. Another device for securing a pervious condition of the ureter is to pass an elastic catheter from the vagina into the ureter, and pass the lower end out through the bladder and urethra. The uncovered portion of the catheter, as now seen through the vagina, is to be covered with the vaginal mucous membrane and the lower urethral wall.

Occasionally a case presents herself where there has been such extensive loss of tissue that all hope of closing the fistula is in vain. The question of closing the vagina (colpokleisis) then arises.

This is to be adopted with great hesitation. Indeed, in this country the experience of the best operators is opposed to it. Continence of urine may be obtained, but, as has been previously expressed, it is only at the risk of constant vesical tenesmus, calculus, chronic cystitis, and all its train of direful consequences. When the base of the bladder, filled with intestines, becomes inverted and protrudes at the vulva, Emmet recommends that enough of the sides of the vagina be united, as in colporrhaphy, to give needed support, but that an opening be left at the most dependent point to allow of free drainage. By proper attention to cleanliness and the use of rubber urinals for females, which can now be procured at the instrument-makers, the patient can be made very comfortable.

James R. Goffe.

VISION, BINOCULAR. Our eyes are surveying instruments, useful to us because they enable us to determine rapidly and with considerable accuracy the position of other bodies in space. The determination of position and space relations is the province of geometry. By the aid of polar co-ordinates we are able to describe and define the position of any point or series of points; and in this way we can describe the work done by the eyes. It happens also that in this way we can best show that part of the work which is done satisfactorily by one instrument alone, as distinguished from that part which is more accurately, more rapidly, and more vividly done by two used in conjunction.

The position of any point in space is known if its distance and direction from another given point is known. Thus in Fig. 5160, if we take O as the origin from which to measure distances and the line O A as the "base line" from which to estimate direction, only two things are necessary to determine the position of any point, as P, for instance, the length of the line ρ and the size of the angle θ. Now, as we stand at the point O with two eyes at our service, we shall find that one of them is capable of giving us very precise knowledge of the size of the angle θ, but two are much better than one in enabling us to correctly estimate the length of the line ρ. In other words, one eye alone gives us direction, while two together give us distance. If this distinction were absolutely and unreservedly true, a person with only one eye would see everything somewhat as on a painted wall, at whatever distance he happened to imagine it, and the visible world would be of two dimensions, while two eyes would give the added quality of depth, and so recognize solidity. On this account we speak of binocular vision as stereoscopic vision. But it is not true that we are entirely unable to appreciate depth by the use of one eye alone. It is only true, as above stated, that we can appreciate the solidity of space more easily and more quickly for having two eyes, and it seems not only proper but necessary to include in the consideration of binocular vision all those functions that are carried on more advantageously by the aid of two eyes than would be possible with one. Narrower limitations would rob the subject of a great deal of the interest that attaches thereto. It would, indeed, be hard to define the function of a pair of eyes as distinguished in any complete and absolute way from that of one, and it is somewhat doubtful if the sensations experienced by the joint action of both differ, except in intensity, from those which are due to one alone. Hence it is necessary for us to recognize the fact that there is in nature if not in name such a thing as uniocular stereoscopic vision, and to examine carefully the methods by which, through the sense of sight, we obtain our knowledge of space relationships, whether that knowledge comes to us through the instrumentality of one eye or of two in combination. First, it is necessary for us to obtain a clear idea of what is meant by the word *projection*, as it is used in explanation of the act of seeing. This word projection has a technical signification, but as often used it covers a multitude of indefinite ideas, and is supposed to carry a load of explanations for which it is entirely inadequate. Our chief difficulty comes to us at the start, and it is in not being able to understand how an irritation produced by any cause whatever acting on the retina, which is a part of our body, should give rise to phenomena which do not seem to us to have any existence in ourselves, but to be situated apart from us in space. And this impression that the thing seen is entirely separated from ourselves, and connected with us in no perceptible way, is something so immediate and obtrusive that we are not conscious of thinking of it as the result of an intellectual process. Neither are we satisfied with the simple assertion that the mind projects the retinal image outward into space. The statement is probably correct, because the word projection, used here in a technical sense, "means just what we mean it to mean," but as an explanation it needs explain-

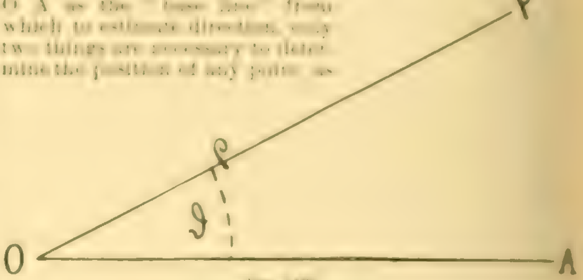

FIG. 5160.

ing. It does challenge attention, this apparent inversion of the common order of events by which a sensation, seeming to have existence in space, is traced by the aid of philosophy to a disturbance of our sensory apparatus; whereas the general rule is that an impression made on our sensory apparatus can only be followed out into space by the aid of philosophy.

This faculty of projection cannot be wholly explained, but it can be classified and shown to be exactly the same mental process by which we locate the disturbances of other sensory nerves, as of touch, or taste, or hearing. When we consider the fact that many of the explanations that we deem satisfactory are merely classifications, we must willingly accept this for the time being, and wait for more gratifying results until we have bridged the gap that separates mental from material processes.

If one wishes thoroughly to understand a machine, let him go to work and make one for himself, or at least try to do so. We cannot make an eye, but we can plan one, and our knowledge of the processes of selection and development will guide us in the choice of material and methods, and after we have finished this imaginary instrument we may hope to have a definite idea of what it will do, and how it does it.

First, however, a word or two regarding our conceptions of space, and our ability to locate disturbances which take place in our general sensory apparatus. It is highly probable that our ideas of space are acquired from experimental realization of the amount of force that is required to move us or our organs from one place to another in response to our volition. Our body occupies space because one part of it refuses to let another part of it pass through, and our idea of its shape is gained from the amount of force which is required to move one part of it until it is stopped by another part, and until we experience the sensation that accompanies the change of state that is produced by these exhibitions of force. Now, our ability to locate a sensation in the end of our little finger when that finger is pressed upon, means that we have a practical knowledge of the amount of force and time necessary to move some other finger until it interferes with the sensation that is going on there, and the concomitant knowledge that the product of the force and time necessary to alter the sensation in the finger pressed upon, by volition directed toward its movement, is practically nothing. We do not mean that we, as highly intelligent beings, have tried these experiments and tabulated the results in our memory, and that we refer to them now whenever we are conscious of a localized sensation. But we mean that we have the knowledge thus gained, and can use it accurately. We may not have gathered it all in by our own personal efforts, but may have inherited it from our remote ancestors, who acquired it gradually while ignorantly resisting the processes of selection. But that we have it, and that it was learned by experience, we do not doubt, and it matters not whether it was our own experience or that of someone else who left to us the results.

Now, after a word or two in regard to the habits of mind by which knowledge is acquired and utilized, we shall be ready to go on in the construction and development of our home-made and artificial eye in such a way that we can see how the habit of projection was acquired, and why we see a thing where it is instead of feeling it upside down on the retina; and, last of all, we hope to obtain an appreciation of what we owe more especially to the binocular arrangement.

There are certain cells in the brain that are devoted to reason and the conscious processes of thought and action. They constitute a kind of "superior court," in which difficult and unprecedented situations are considered and acted upon. There are certain other cells or collections of brain-tissue that receive all messages from the periphery, and transfer them to that part presided over by consciousness, from which, in turn, they receive orders and execute them according to directions. This second class of cells seem to have a certain independent ability to act of its own accord, and to take an independent part in the management of the animal economy; but it acts only by precedent, as a court of common law, and when messages of exactly the same import have been received a certain number of times, the answering appreciation of their significance takes place in a mechanical way, and the necessary orders for action are given even before there has been time for the transmission of this intelligence to the cells where the highest processes of thought go on. Besides all this, that part of the brain first mentioned, after a certain time and a certain amount of experience, absolutely refuses to take cognizance of this routine work. At first it merely recognizes the action that has taken place, and then forgets, and after a while it is absolutely unconscious of the whole routine, accepts the results as reliable, and pays no attention to the detail by which they were collected.

This may not be the most modern and elegant way of stating the laws of mental physiology, but it is near enough the truth for our present purposes, and must be remembered while we watch the development of the eye as an organ specially adapted for the reception of impressions which we find so useful in giving us knowledge of what is taking place in that part of space which is removed from immediate contact with the material of which we are made. In consideration of these facts the localization of a sensation in space is no more to be wondered at than its localization on some part of our body. The fact that we feel at the end of our finger means that the sensation which is there located has come to us so often that the reasoning process necessary to discover the cause and its situation has taken place so many times that it has become a mere matter of routine, and has so dropped from consciousness. The precedents have been so well established by uniformly unvarying results that the matter is decided by the class of brain-cells that act only by precedent. The causes that produce sensations in the finger are multiple. We can trace them to their source, but the sensation itself gives us absolutely no means of measuring distance with anything at all approaching to accuracy beyond the finger itself. The finger is at the end of the beaten track, beyond which it is a matter of exploration for every separate sensation. There seems to be no reason to doubt that, if slight variations in digital sensation were always caused by slight variations in the distance from the finger at which the disturbing element was situated, and if the distance and direction varied with the sensation so constantly that we could put absolute dependence on their significance, we should locate them just as we do visual impressions. There seems to be some slight approach to such location when the point of one's pen scratches over a rough surface in the paper, or when one is walking on soft snow which collects on the sole. Why should this not be the case? We do not think with our arm. We are not conscious with it. It is nothing but a prehensile apparatus having a telegraph system in it, and, as far as consciousness is concerned, it is as decidedly removed from us as the end of our fishing-pole. Sensations from the skin are not actually felt there; they are carried to the brain before we know anything about them, and we can measure the time that it takes them to go. Neither have we any reason to think that the sensation is sent back from the brain to the end of the finger; but, as we said before, it is located there because that is the end of the beaten track over which our mental search for a cause always leads us, and not because a nerve runs out toward it. The nerve has a different function, namely, that of carrying the sensation to the brain and the motive impulse back. If other sensations are as unvarying in their significance regarding some other points farther removed from us in space, the beaten track is extended and the sensations correctly interpreted, in accordance with the same laws which have formerly put it on the end of our finger, or at any other place to which it has been referred.

Perhaps this will seem to be a bold conception to one who has never thought of it before, but it is not without parallel in the every-day experience of all. Space does not permit of any illustrations, except such as are given in passing in reference to the eye itself.

It is generally conceded that the organs of special sense have been gradually and slowly developed from the general sensory organ situated in the skin. Let us take a small portion of the skin surface and without trying to follow closely the actual processes that have gone on through past ages, we will see how much can be done, within the limits of probable variation, toward making it into an organ that will delicately appreciate differences in sensation that are connected in an unvarying manner with differences in direction and distance of the originating disturbance. And we will do this with the full expectation that the mind will locate the sensations caused by these disturbances as far away from the central organ as it can go without leaving the beaten track which it has always and invariably been obliged to follow in its search for a cause.

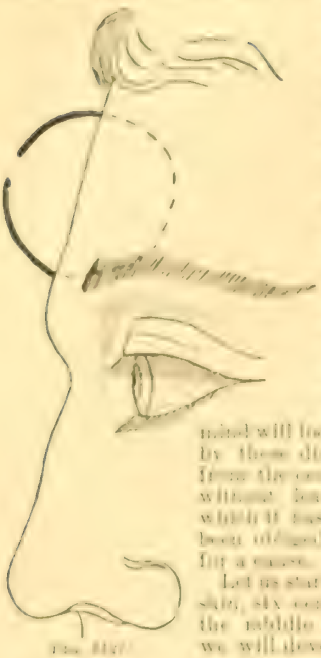

Fig. 5127.

Let us start with a circular patch of skin, six centimetres in diameter on the middle of the forehead, which we will devote to the estimation of the direction and distance of objects that can affect it only through some intermediate substance. In order that it may be devoted especially and exclusively to this work, we will suppose it to be covered over by an inverted vessel about the shape of a teacup, which has a hole in the bottom about one centimetre across (Fig. 5127). There are various influences that can reach this sensory surface through the opening that has been left in the artificial covering, viz., grains of sand however put in motion, drops of rain blown by the wind, puffs of air, whether coming singly or at regular intervals like small waves, some of which it will appreciate, or the finer and more delicate waves of radiant heat. It will be seen at a glance from Figs. 5129 and 5130 that if we but choose such disturbances as travel only in straight lines, we shall have already an instrument that will estimate direction with a good deal of precision, for on the forehead we can distinguish between two irritations that are taking place within one centimetre of each other, and the area of the surface exposed being about twenty-eight square centimetres, we shall have at least twenty-eight distinct sensations that will indicate with certainty as many directions that may be occupied by the body originating the disturbance. It seems almost impossible to imagine that one should be constantly using one's judgment about the significance of impressions of this kind, without very soon doing it in an automatic way without the activity of those cells that preside over consciousness being excited; this is quite in keeping with what goes on in regard to other things. No one who has learned to read, to write, to walk, or to ride on a bicycle, but can recall the various stages passed through in some of these acquirements, from the time when the work was wholly directed by the intelligence, and laboriously directed, too, until the time when we read, we walk, we ride, and do not know how we do it, and do not even know that we do it. Ideas come to us from the printed page, for hours at a time, without our having the slightest consciousness that we are using syllogisms, that words are intricate combinations that stand for sounds compound in their nature and complex in their significance, and which we were once obliged laboriously to decipher, although now we do the work without the slightest consciousness that there are such things as words, or books, or ink, or paper. Further illustrations are as unnecessary as they are abundant, and they all teach us that all mental operations that can be made a matter of routine and precedent become unconscious operations, and the world presents itself to us as a vivid and real thing of such a nature as it has proved itself to possess by intellectual processes after these processes have reached the end of the beaten track, whether that track has been worn to the end of the finger or to the end of the street. It remains only to show that the eye is an instrument whose measuring functions are so accurately performed that they never mislead in their indications of what exists in visible space, though they never suggest to us that there are such things as images on the retina; and the wonder becomes, not that we should see a thing where it is, but that we have ever found out that there is such a thing as a picture of it on the retina.

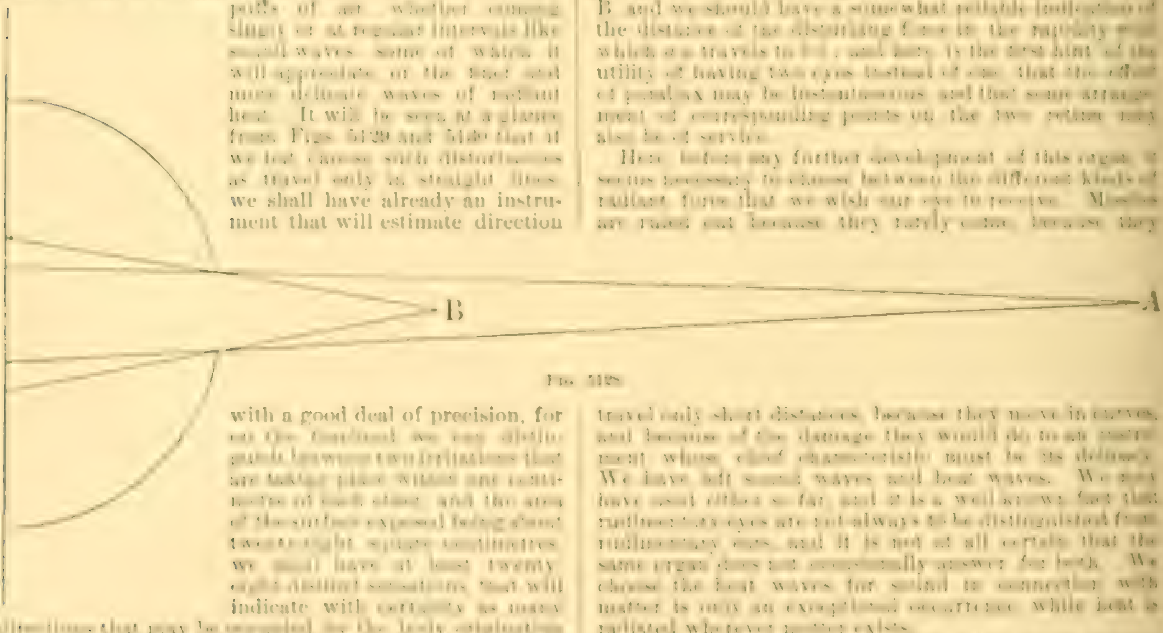

Fig. 5128.

Returning now to the diagrammatic eye as shown in Figs. 5128, 5129, and 5130, we have in this clumsy instrument the first suggestion of an ability to estimate depth as well as direction. In Fig. 5128 it will be seen that forces coming from a point near the eye, as at B, will impinge upon a larger part of the sensitive surface than those coming from the point A, which is farther removed. But this is of doubtful significance, as a number of points near A (Fig. 5129) would produce about the same effect as one point at B; but if the eye were moved from side to side, the position of A, in Fig. 5130, would change as that of B, and we should have a somewhat reliable indication of the distance of the disturbing force by the rapidity with which one travels in [illegible], and here is the first hint of the utility of having two eyes instead of one, that the effect of parallax may be instantaneous, and that some arrangement of corresponding points on the two retinæ may also be of service.

Here, before any further development of this organ, it seems necessary to choose between the different kinds of radiant force that we wish our eye to receive. Missiles are ruled out because they rarely come, because they travel only short distances, because they move in curves, and because of the damage they would do to an instrument whose chief characteristic must be its delicacy. We have left sound waves and heat waves. We may have used either so far, and it is a well-known fact that rudimentary eyes are not always to be distinguished from rudimentary ears, and it is not at all certain that the same organ does not occasionally answer for both. We choose the heat waves, for sound in connection with matter is only an exceptional occurrence, while heat is radiated wherever matter exists.

We have used the term heat guardedly, for heat as such is perceived by the sensory nerves of the skin, and the heat waves and light waves are not merely similar, but they are absolutely identical. This is a well-known fact in physics, though it is often ignored or passed over lightly in elementary books; and as the eye is supposed to develop from a surface that is well known to be sensitive to heat as heat, and as the pigment spot which is usually present increases the heating effects of the ray, it is not improbable that the heating effect of the ray has much to do with the early growth of the organ.

We will then accept the choice that nature has made for us, and hereafter we will exclude all other disturbing elements, and consider that the eye is adapted to the reception of those waves that fall between A and H, as designated by Fraunhofer.

Next, suppose we place in the aperture of our cup-shaped organ an arrangement that will cause all rays that pass through it, after diverging from a point, as in Figs. 5131 and 5132, to converge to a point on our sensitive surface that corresponds to the retina. Such an arrangement is the lens that we have in the human eye, and it must needs change its shape to correspond to every different distance of the point of radiation, and, as is well known, it must be of greater thickness for B in Fig. 5131 than for A in Fig. 5132. This change being dependent on voluntary muscular action, the force of which we are able to feel, we have now the ability to judge much more accurately concerning depth or distance, that is, concerning the length of the line ρ in Fig. 5126, by the effort that is necessary to make the spot on the retina as small as possible.

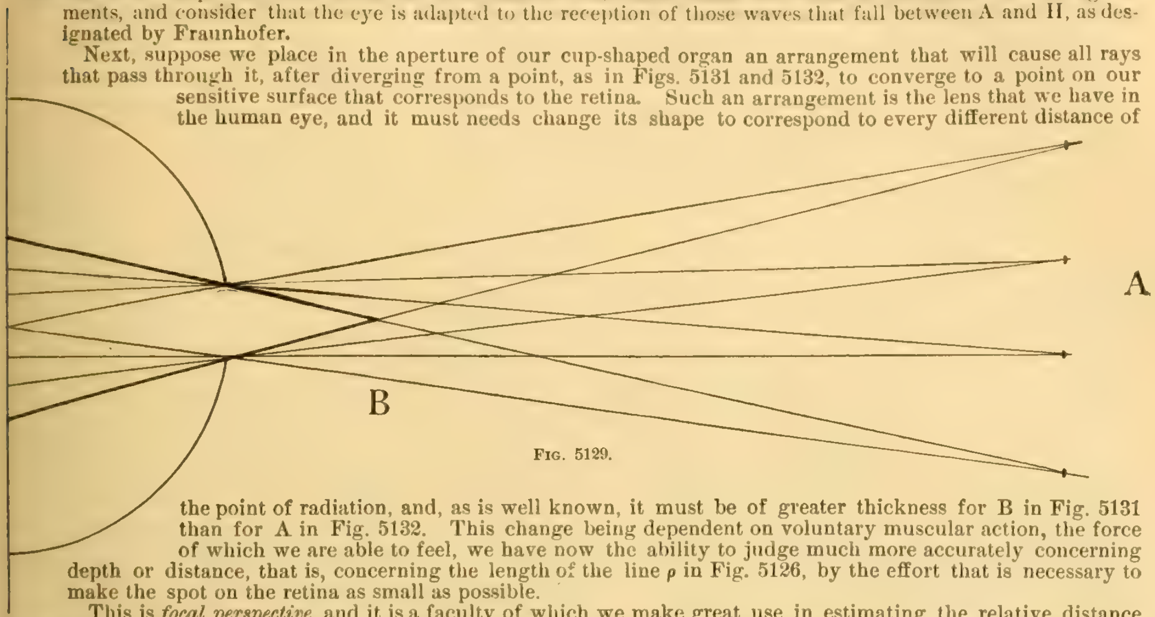

FIG. 5129.

This is *focal perspective*, and it is a faculty of which we make great use in estimating the relative distance of objects that are less than twenty feet away. Beyond that distance, changes necessary in the lens are so small that we cannot appreciate them. The eye has also, since this last modification, acquired two other methods of estimating distance, by which it can reach out still farther into space and make unerring inferences. One is *mathematical perspective*. It depends upon the fact that any number of points situated near each other in space are represented on the retina by a similar number of points similarly arranged; and though our personal experience never allows us to find out about these retinal points, the sensations caused by them are distinct in their character, and unerring in their significance regarding the position of the points that are causing these latter by their radiations; and if we or our ancestors have ever had the ability to locate the originating points consciously and theoretically, it follows that we must, in accordance with all experience in similar matters, soon come to locate them unconsciously, after our experience has been such as to establish the trustworthy nature of our deductions; and we locate them in space because we find by experience the cause of them in space; and we do not locate them on the retina because we, in our personal experience, have never had any reason to think that we have a retina, much less a geometrical arrangement of points on it. This sensory surface, which is fast developing into a retina under our guidance, is not only able to recognize difference as in the location of the light points, but has become extremely sensitive to gradations in the intensity of the irritations that are directed to it; and as all points which mark the special limits of material objects are likely to vary in their light-giving qualities, and as none of these variations are matters of chance, but many of them depend on the shape and situation of the bodies themselves, we have in the eye as here constructed an instrument that is quick to detect the changes of form in the retinal image, though it cannot recognize them as such, but must attribute them to a changed arrangement in the outlines of the body that is the source of the disturbing radiation.

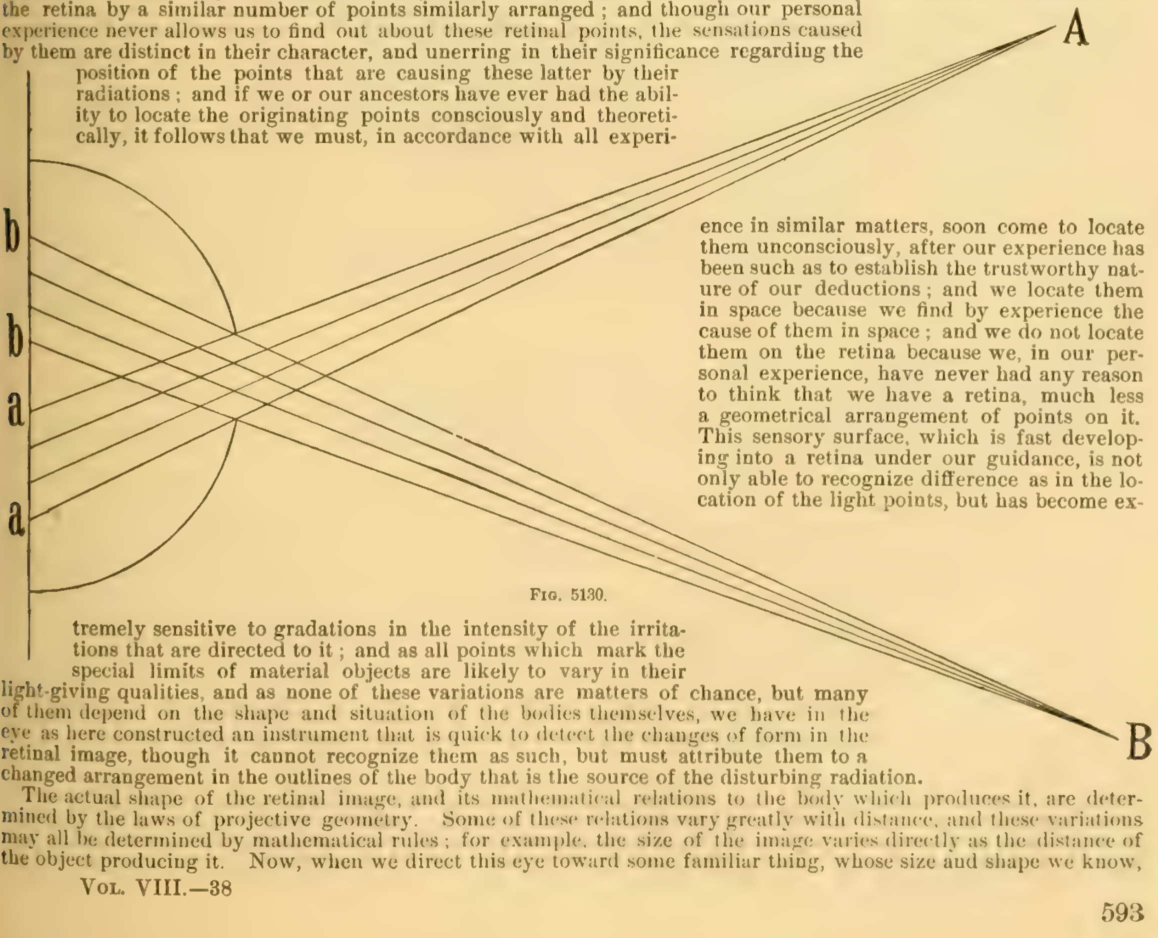

FIG. 5130.

The actual shape of the retinal image, and its mathematical relations to the body which produces it, are determined by the laws of projective geometry. Some of these relations vary greatly with distance, and these variations may all be determined by mathematical rules; for example, the size of the image varies directly as the distance of the object producing it. Now, when we direct this eye toward some familiar thing, whose size and shape we know,

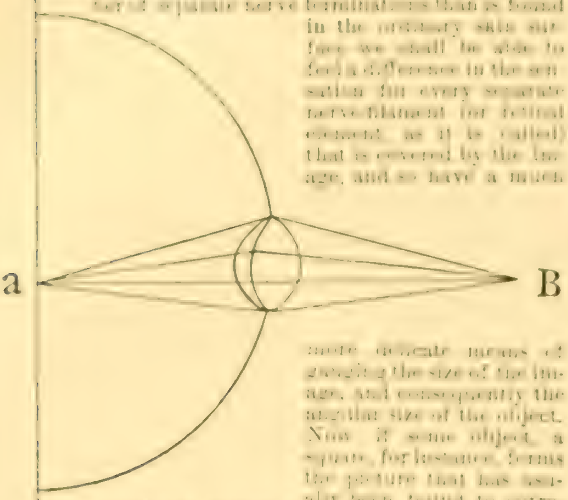

Fig. 5151.

experience teaches us that certain changes in its apparent shape from what we really know it to be are dependent wholly on distance; and if we have, as in Fig. 5151, a much larger number of separate nerve terminations than is found in the ordinary skin surface we shall be able to feel a difference in the sensation for every separate nerve filament (or retinal element, as it is called) that is covered by the image, and so have a much more delicate means of gauging the size of the image, and consequently the angular size of the object. Now, if some object, a square, for instance, forms the picture that has usually been found to correspond to a square at a certain distance, we see it as a square at the distance at which it has heretofore been proved to be. It may not be a perfect picture of a square, but if it is nearly enough so to be decidedly suggestive of a square, and the only difference is that one side of it does not seem to be quite long enough; after we have found out that it ought not to seem quite long enough if it is a little farther off than the other side of the square we shall soon get to recognize that it is a square, but that one side is a little farther off than the other; and after a time this will not be the result of deliberation, but it will be our first impression, because that philosophic process has become a matter of intellectual routine and is dispensed with or attracts our attention no more. These impressions, which are in adults instantaneous, are what we know as *mathematical perspective* because they are impressions that are caused by a practical though not necessarily a theoretical, mathematical knowledge of the situation. The fact that our habit of unconsciously making allowance for the mathematical perspective continually warps our judgment in regard to the real shape of the picture on the retina will be readily appreciated by any one who has taught drawing from nature, and found the difficulty of making pupils draw what they see instead of what they know is really before them; and this too illustrates how quickly the consciousness ceases to interest itself in the application of general rules that have been found to be invariable. We have also in the eye a power to appreciate what may be called the translucency of the stereoscopic picture and which will be mentioned later. Thus, if we direct the eye toward three points in the same straight line, but at such different distances that when the middle point is focussed the other two will make comparatively large circles of diffusion on the retina, and if the angular distance of the points be very small these two circles of diffusion will overlap each other and also overlap the middle point that is distinctly focussed, and the retinal picture as well as the visible picture will be like Fig. 5154; then as we get the parallax by moving the head a little from side to side while the eye is fixed upon the point, the smaller circle will move as we move the head and the larger in the opposite direction. This will suggest to us that the smaller circle is behind the point and that we see the point through the larger circle. This phenomenon also suggests depth, at first through our intellect, afterward instantaneously; and in this way we can analyze the impression which we get in looking at an object in front of or behind a dingy glass, or a transparent screen or netting. *Aerial perspective* also gives us a criterion by which to judge of distances that are greatly different.

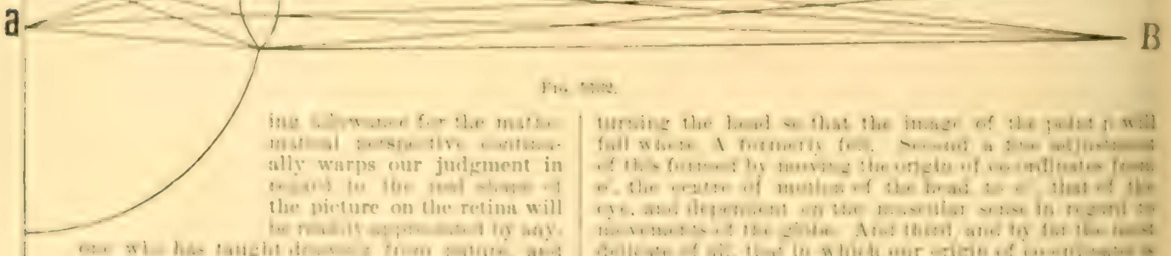

Fig. 5152.

The opacities of the air cut off the light, and the irregularities of density change its direction so that points and lines cannot be accurately focussed; and, in consequence, coarseness and irregularity of outline also suggest distance and vary with the distance.

It will be an easy step now to make the transition from the instrument that we have imagined ourself to develop from the skin to a fully formed human eye (Fig. 5153). The shape has somewhat changed, the concavity of the retina being nearer the shape of the real image that it receives than a flat surface would be. The number of elements in the retina are immensely increased, so that the ability to estimate angular magnitudes is in its most sensitive part delicate enough to appreciate fractions of a second. The whole organ is made mobile, and furnished with muscles that will direct it to any source of radiant disturbance, and through the ages it has acquired so many methods of judging of distance—that is, of estimating the line *ρ* as well as the angle ω—that through it we get the most definite and trustworthy information of the outside world, while we get no information as to what is going on on the sensory surface itself. Let us review the situation, and see what we have in the normal eye as far as ability to judge of space relations of external objects is concerned; that is, what power we have at our command for obtaining accurate information of the position of objects in space, using our polar coordinates for the description of positions, and remembering that form is entirely dependent on position. Considering Figs. 5155 and 5156, we shall see that for measuring the angle ω, or the angular distance of p from any point A, there are three methods. They may be named as follows:

First, that dependent on the muscular exertion of turning the head so that the image of the point p will fall where A formerly fell. Second, a fine adjustment of this former by moving the origin of coordinates from o, the centre of motion of the head, to o', that of the eye, and dependent on the muscular sense in regard to movements of the globe. And third, and by far the most delicate of all, that in which our origin of coordinates is placed at o'', the nodal point of the dioptric system, and the arc $A''\,p''$ is measured by the number of retinal elements that are included between the points where the lines $p''\,o''$ and $A''\,o''$ cut the retinal surface.

For the determination of the length of the line *ρ* we have more but less accurate methods. First, in *focal perspective*, connected with the muscular sense in the adaptation of the lens to the distance, so that small and distinct images can be obtained. Second, in the transparency of the circles of diffusion, or our ability to see through images or parts of images that are indistinctly formed, and our disbelief in the possibility of having two objects occupy the same place at the same time. Third, in *parallax*, a practical knowledge of the relative changes in angular distance that will be produced, in bodies at different actual distances from ourselves, by change in our own position. Fourth, *mathematical perspective*, or a knowledge of the discrepancies that a difference of actual distance may cause in the results obtained as above, when compared with each other or with what we know is the actual state of the case by experience obtained through the other senses. And fifth, *aërial perspective*, or the changes due to a lack of transparency or homogeneity of the medium through which the object is seen. It is thus seen that we have for the angular distance, as when we stand at O and estimate the distance A P, in Fig. 5126, accuracy to within a fraction of a second.

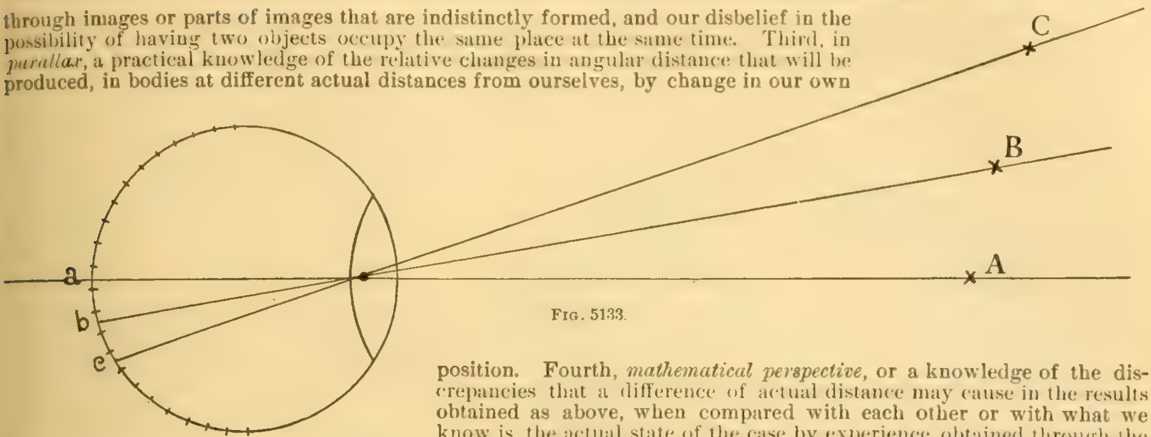

FIG. 5133.

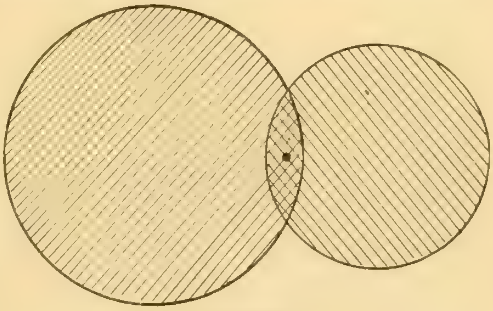

FIG. 5134.

For the measure of the actual distance of an object from ourselves, as of O from A or from P, we have no one method at all comparable for accuracy to the above, in which, by the mobility of the eye and the fine distribution of retinal elements we have five different methods, each one of which produces its own impression as to the length of the lines, and by combining them we have a resultant that should be expected to compare in accuracy to those obtained from all our other senses put together.

When we compare the sense of sight to that of sound, we cannot wonder that our impressions of space that are gathered from the former sense should be quite as vivid and precise as they seem to us. In listening it is highly probable that the ear is put in one and the same condition for sounds from all distances, uniaural adjustments being only adapted to the estimation of pitch and intensity, neither of which are invariably dependent on distance, so that we have nothing that corresponds to focal perspective; and though we are perhaps as well off in regard to the aërial modifications as in the eye when we compare definite sounds with definite points of light, we lose all this advantage, or, at least, nearly all, from the fact that audible vibrations are of extremely rare occurrence, while every point in the boundaries of material objects is a source of those vibrations by which the eye may judge of distance; and this judgment is immensely aided by comparisons that can be made, at the time of the effect produced, by any one point or any series of points, and that produced by others, and we scarcely open our eyes but there is presented to us examples, visible points, lines, and surfaces, situated at any and all distances that we can imagine to exist, and we can note and do, both consciously and unconsciously, the gradation of these effects one into another, especially in looking at lines and surfaces, whereas in sound we have nothing of this effect, except where the element of time is added we may, as when a moving sound dies away in the distance, realize it by the variation of intensity.

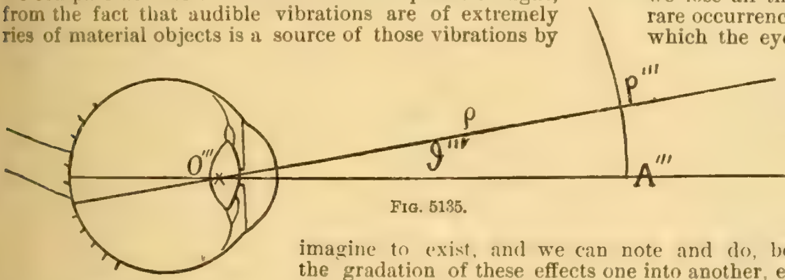

FIG. 5135.

If the writer has succeeded in setting forth in an intelligible manner the very important part that is played by a single eye in giving us instantaneous ideas of the space relations of distant objects, he feels that a great deal has been done preparatory to the study of binocular vision, which is only a study of the method by which two eyes refine and intensify the ideas of solid space which we receive in great measure from one eye alone.

He will apologize, if apology is necessary, for devoting so much attention to a single eye, but he feels sure that the binocular function cannot be understood and appreciated without a comprehension of the fact that there is such a thing as uniocular stereoscopic vision, the theory of which needs to be more thoroughly examined than it ordinarily is in elementary works.

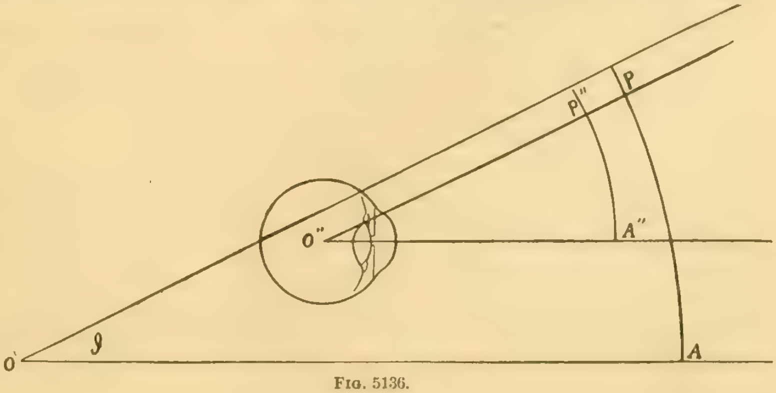

FIG. 5136.

The perpetuation and present existence of a binocular system in all the higher orders of animals is probably due to the fact that by it the field of vision is enlarged. It

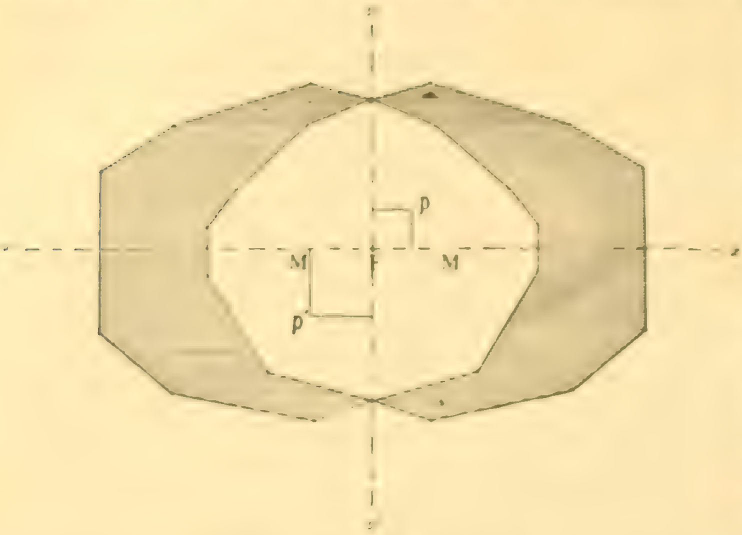

FIG. 5137.

is highly probable that in many animals this is the only advantage, and that the fields do not overlap, but that the one begins on the picture somewhere near the place where the other leaves off, and so the binocular field is just double the extent of the uniocular. In this case there is no more need of confusion from the existence of double images than there would be if the animal had a cyclopean eye of double the angle of aperture. In the eyes of those animals where the fields overlap a little, and some objects at the extreme front are seen with each eye, it is impossible for us to believe that the animal would be deceived for any length of time into thinking that there were two objects instead of one, and it is natural for us to suppose that the central point of that part of each field which is overlapped by the other should be the one on which objects that were immediately in front of the individual would be focussed, when the eyes were at rest and were not making any special effort to see. Fig. 5137 represents the two fields of the human eye taken when the eyes are so directed that the axis of symmetry of each eye is very nearly identical with the general direction of the axis of the orbital cavity. The centre of the right field is at M, that of the left at M, and these two points are at an angular distance of about twenty-five degrees, this being a little less than the inclination of the orbital cavities. This diagram also just as truly represents the sensitive surfaces of the retinæ seen from behind as one looks at the focussing plate of a camera, and overlapped as they would have to be to receive the same retinal image from one lens that they now receive from two. Any point of light directly in front of the observer and at a great distance away, will, of course, fall upon the point F, and F will have the same anatomical situation on each of the retinæ; and in the neighborhood of this point is the place where most of those images would fall to which we desire to give particular attention. Now, following the same laws that have been so particularly insisted upon in the last section concerning vision with one eye, and which now may be taken for granted, it is impossible to suppose that we should fail to recognize that there was only one object to correspond to the sensation that was caused by the simultaneous excitation of both retinæ at those points where they would be most likely to be affected at the same time. As this is the point near which the images of objects in the "approaching view" will naturally fall, and will be focussed at first without any effort on our part, it is of course the point at which the function of vision will be most frequently exercised and most carefully cultivated, and this is in fact the point where the retinal elements are the most numerous and the most sensitive. Further, if the point F be taken as the origin of coordinates (rectangular Cartesian coordinates are the most convenient for our purpose here), we can plot out by the laws of projective geometry the exact positions that the different parts of the retinal pictures will occupy if they are caused by distant objects in the binocular field. It is evident at a glance that those points that fall on the axis $y\,y$ will be the only ones that will have the same anatomical position, while all others will be as far to the inside on one retina as they are to the outside on the other. The points on the two retinæ that correspond to the same coordinates are called corresponding points, and objects forming images whose positions are marked out by corresponding points on the two retinæ are seen as one. This is *the law of corresponding points*, and was first stated, as far as we know, by Alhazen, an Arabian philosopher who flourished about A.D. 1100. Vision, as ordinarily measured by test letters in the binocular field, is undoubtedly more acute when both eyes are in use, but the difference is so slight that it is hardly worth noticing. A change amounting to five per cent. in the dimensions of the object looked at, or in the illumination, will probably more than compensate for the loss of one eye under these conditions; but in the estimation of actual distance

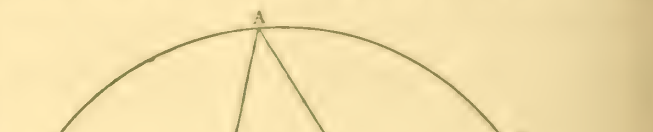

FIG. 5138.

of the object from the observer, the advantage that two eyes have over one is very great. Let us suppose now that we have finished with our rudimentary experimental eye, and that we have two eyes fully formed and well developed into their present condition, as they now exist in the human species, and that we are thoroughly acquainted with the abilities of each in a unocular way. Remembering that they are surveying instruments, and that in their natural situation one is permanently placed at each end of a base line which is in the same individual practically fixed and unchangeable, and in the adult is between six and seven centimetres in length (see Fig. 5138), S D representing the base line or the intra-ocular distance, which, without any great error, we may assume to be the same whether it is measured between the nodal points or the centres of motion of the two eyes.

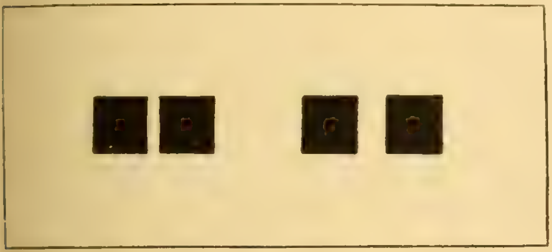

Fig. 5139.

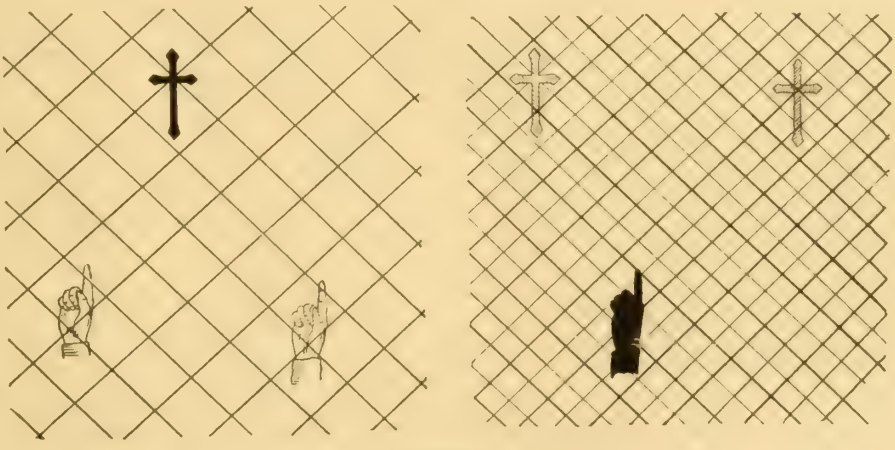
Let a and a′ be the most acute part of the retinal surface, viz., that part which is likely to be the most thoroughly cultivated in any animal that has the power of locomotion, because it is the part naturally turned to the approaching landscape when the eyes are at rest. Remembering the law of corresponding points, it will be seen that if the attention is directed to any near object as A, it will be necessary to turn the eyes inward, so that the visual axes will make at the points S and D two angles that are together less than a right angle, these two angles being practically right angles for distant objects. The estimation of the perpendicular distance of A from the line S D becomes an easy problem in surveying, it being a trigonometric function of the angles A S D, and A D S, and the magnitude of each of these angles is quite accurately estimated by the muscular sense of the force required to converge the eyes so as to bring the image of A on corresponding points and on the most sensitive portion of the retina. That the appreciation of the amount of muscular convergence is an important element in the binocular estimation of distance, is well shown by Fig. 5139, which is a reproduction of a stereoscopic card published by Dr. John Green in the "Transactions of the American Ophthalmological Society" for 1889, illustrative of the fact that the slight amount of convergence that is necessary to superimpose the two right-hand squares is enough to overpower the impression made by all the other conditions combined, and to convey to us the idea that the right-hand square is both nearer and smaller than the left, though this is not at all the case. Hence we may put it down as a fact that one of the chief factors in the binocular estimation of distance is the amount of convergence necessary to bring the two images over corresponding points of the retina.



A Fig. 5140. B

Note.—All the reproductions of stereoscopic pictures in this article may be seen as they stand in the book, by changing the direction of the optic axes so as to obtain just that amount of diplopia, either homonymous or heteronymous, that will bring the right-hand picture of one eye over the left-hand picture of the other. Anyone who has not acquired this art may readily do so with the help of a No. 2 prism (base out or in as the case may be), the relative distance of the different objects being exactly reversed as the díplopia is made homonymous or crossed.

Before going farther it will be necessary to make some inquiries into the nature of the sensations produced by objects so situated that they do not produce images that fall on corresponding points. Perhaps a single experiment will be sufficient for our purpose. If we point with the forefinger at some distant object, a cross on a figured wall for instance, and look at the cross at the same time, we shall see it distinctly, but we shall also see, if we have self-control enough to prevent our eyes following our thoughts, that there are two fingers pointing at the cross instead of one. One of the fingers will seem to be directly in front of us, and the other will be seen a little to one side, or it may be that we shall see the cross in the distance directly between the two fingers. Those of us that have had the pleasure of being boys and using bean-blowers, have a distinct recollection of taking aim between two apparent tubes when we really had but one in our hands. These indistinct images of the finger that we see hide nothing, because of the different relative positions occupied by the two eyes, that which it hides from one not being hidden from the other (see Fig. 5140, A). If now, without changing our position, we look at the finger, we shall see that distinctly, it no longer being doubled, but we shall also see two crosses, and the figured wall in the distance will also be doubled (see Fig. 5040, B). Nothing on the wall will be hidden from us because that which is covered up in one image of it will be uncovered in the other, and one eye will see what the other does not. This is a phenomenon which reminds us of the transparency of the circles of diffusion in uniocular vision, though it is much more marked. However, it is a thing which quite a number of people have never noticed, and which some few cannot be made to see. The position of the eyes and the objects in this last experiment is seen in Fig. 5141, where C corresponds to the finger when we look at the cross at B, and where A corresponds to the cross when we look at the finger at B; A, B, and C representing objects at three different distances in front of the observer, and in the same—nearly horizontal—straight line a little below the level of the face. Each eye is supposed to be looking at B, and when so doing C is seen faintly on the left by the right eye, and faintly on the right by the left eye; while A is seen faintly on the right by the right eye and on the left faintly by the left eye. This apparent doubling of the object is called diplopia. When the apparent place of the object as seen by the right eye is on the right of where it ought to be, and that of the left on the left, it is called homonymous diplopia; when the object as seen by the right eye is on the left of its true position and that seen by the left is on the right, it is called heteronymous or crossed diplopia; and from Fig. 5141 we can establish a general law that all objects beyond the point toward which we direct the visual axes will be doubled homonymously, while those that are nearer than that point will be doubled heteronymously. Fig. 5142 presents the appearance of the three objects A, B, and C arranged as in the last figure when the eyes are looking directly at B. B is seen distinctly, while C is doubled, and each of the apparent Cs are seen more faintly and neither of them completely hides what is at a considerable distance beyond it; and the apparent A is also doubled, the As being seen somewhat indistinctly, and nothing on the plane surfaces perpendicular to the visual axes at the same distance as A is entirely hidden by B or C. When the eyes are directed toward B there are other points in space where objects may be placed so that they will form images on corresponding points of the two retinæ, but these places are not directly behind or in front of B. They are situated either above or below, or toward one side, and the locus of these points is called the *horopter*, of which something more hereafter.

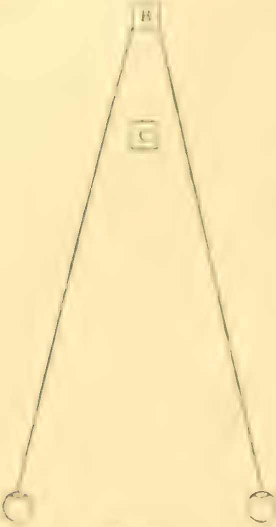


Fig. 5141.

One other, and a highly important, fact must also be mentioned before we have the data necessary to follow out the methods by which we obtain binocular impressions of space. It is this. The laws of projective geometry teach us that any solid bodies that are differently situated in regard to the two eyes must generally produce two retinal images that are not absolutely identical, and the dissimilarity will have an inverse relation of some sort to the length of the perpendicular distance from A (Fig. 5138) to the base line S D as compared with the length of the line S D. That this difference which must necessarily exist between the two pictures had something to do with the perception of solidity in space was probably known to Leonardo da Vinci. He is credited with having had some appreciation of the facts, but they did not attract much attention in the scientific world until the days of Wheatstone, who again called attention to them, and proceeded to demonstrate that, hidden behind these two dissimilar pictures, might be found the germ of much that even to this day goes by the name of binocular vision. He did this by the invention of the stereoscope, an instrument by which that difference which exists in a marked degree between the appearance of the outside world as viewed by two eyes and as viewed by one eye alone, is so completely simulated that no one since has been disposed to doubt the radical truth of his views.

The stereoscope is an instrument by which two pictures, both drawn on a plane surface, and differing from each other just as two projections of solids or groups of solids would differ when projected on the same plane surface through two points as differently situated as the two eyes usually are. Let us illustrate by a somewhat exaggerated picture. If we hold a small book with the back toward us about one foot in front of the face and in the median plane that divides our face symmetrically, and if we look at the book with the right eye we shall see something like R in Fig. 5143, but if we look at it with the left eye we shall see it as it appears in L. The same difference in the two pictures will appear in a less degree if the book is at a much greater distance from us than it is in this particular case. We shall see the back of the book with both eyes, and the pictures on the retinæ will be similar in this respect, or nearly so; but with the right eye we shall see the right side of the book, which is entirely invisible to the left eye, and with the left eye we shall see the left side, that is entirely invisible to the right eye. Each of these pictures is exactly like the projection on a plane surface perpendicular to the visual axis and situated anywhere between ourselves and the book. Now, if we direct our attention to the back of the book, we shall see that distinctly, and it will appear single because it will in the main form retinal pictures on corresponding points; the rest of the book, that is, the two sides, will not be seen as distinctly, for their pictures do not fall on as sensitive portions of the retinæ, and we shall see the two sides in two different places from what we know them to be. We may not notice this if our attention is not called to it, but if we look carefully and analyze the sensations that we are receiving, this book, that appeared to us as one solid book shut together and confined as closely as its thickness would permit to the median plane, will be two books somewhat shadowy and having a common, real-looking, and apparently solid back as it appears in L-R. If now we direct our attention to the further extremity of the top of the book, which seemed indistinct and double before, we shall see that as in R-L it is no longer dim and indefinite, but it is now single as it ought to be, while the back that is toward us is now double, and we half feel as if we saw parts of each side through the other. Besides all this, the book does not seem to hide the things in the room beyond it. We do not think of it as being transparent, but whatever we look at a little distance beyond the book can be plainly seen, sometimes through one of the books (it has now become entirely doubled), sometimes between them or off at one side. All these things we can see with a distinctness corresponding to the part of the retina on which their picture falls, if we keep our eyes fixed on the book itself. This practical transparency is enough in itself to suggest that the book is in a different plane from other things that seem to be behind or in front of it and can be seen at the same time. Life-long experience when the real distance of the two objects

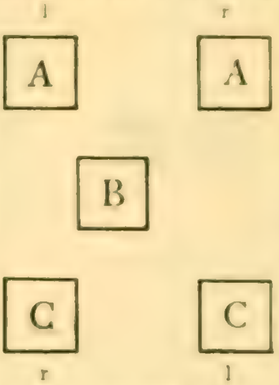

Fig. 5142.

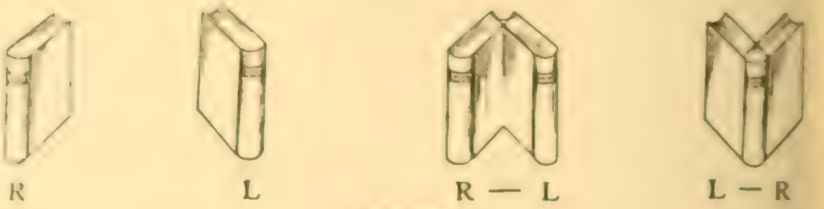

Fig. 5143.

looked at was the same, has only produced this effect in case of certain exceptional substances, glass for instance. The double outline of one part of the book, when we look at the other, is also a phenomenon that is almost entirely confined to appearances connected in our experience with solidity. Referring again to the experiments with the hand and the cross, let us review the binocular phenomena thus far studied. We have the muscular sense necessary to convergence when we direct each visual axis to the thing looked at. With the hand and the cross (Fig. 5140) we see that two objects that are situated at different distances in front of us cannot both be seen singly at once, and by comparing with Figs. 5141 and 5142, we see that the further object is doubled homonymously, and that the nearer is doubled heteronymously, while that at which we look is seen singly. We see also that nearer objects do not necessarily, if small, conceal the more distant ones—what is true of them as above stated is also true of different parts of the same object. In these four facts we have all the important data needed to explain the superiority of binocular over uniocular perception of space relations. No one who has binocular vision will hesitate to say that the difference between the view as seen by one eye and by two is strikingly vivid, as, considering these advantages, it ought to be. In convergence we have, of course, a great improvement on the parallax. In the doubling and the transparency of the images we have that of which the looking at objects from different positions, and the blurring of their edges from circles of diffusion, is merely a hint.

Great as these advantages are, singly or together, it has not always been a matter of universal agreement as to which played the most important part in giving the added usefulness. Wheatstone, the inventor of the stereoscope, asserted that our perception of the third dimension in space was to be explained in this way: That the two eyes receive two images slightly different on each retina, and the two images are fused by mental processes. This is the first great step that was taken in the scientific development of the subject, and it contains the gist of the whole matter. Just what Wheatstone's ideas were and how expressed, the writer is not at the present moment able to state, but the idea of mental fusion seems either not to have been so broadly and comprehensively used, or else to have been so little analyzed and explained, that it was not accepted without criticism. Professor Le Conte, in a somewhat recent book, says of this theory, "It makes simple and primary that which is capable of analysis into simpler elements." This is undoubtedly true, but whether in the act of seeing this analysis always takes place before or while we are experiencing the binocular perceptions is a question that may be considered as to-day open to argument. If, whenever we look at solid objects, our visual sensations are varied from uniocular sensations simply by the fact that there are two slightly varying pictures which nearly but not quite fit the corresponding points, there does not seem, in the light of modern ideas in matters of mental physiology, much reason to doubt that our appreciation of solidity would be increased considerably whether we were able to analyze and systematize the variations or not. After Wheatstone, the experiments of Brücke, Brewster, and Prevost proved that the double images are not ordinarily so completely fused that careful attention to the appearances does not enable us to appreciate that they exist, and so produce consecutively single vision for all points in the binocular field, even if they are not included in the same horopter. This school taught that this state of things is somewhat appreciated in a functional way, and that the eyes are in a state of unconscious changing, the adjustment being rapidly altered to fit various different points in turn, so that the resulting impression is a feeling of depth equivalent to the requisite amount of change. This theory may be considered to be an advance on that of Wheatstone, not on account of its disproving that, but because it gives additional detail, and analyzes a process that undoubtedly goes on in certain cases; but the theory is wrong as teaching that this process of continued change from one point to another is a necessary or constant part of binocular vision. The fallacious part of this theory was afterward shown by Dove, who proved experimentally that the binocular stereoscopic effect may be instantaneously produced, and does not need the time necessary for the execution of these movements. It was asserted by Dove, and has been abundantly verified by experiment, that the illumination by a flash of lightning or by a spark from a Ruhmkorf coil, the duration of which is so exceedingly short—less than one two-thousandth of a second in some cases—that the idea of changing the adjustment of the eyes is out of the question. Still, there is no doubt that we do at times reassure ourselves in this way in regard to a stereoscopic effect; anyone in experimenting with binocular vision will do so many times consciously, and will catch himself in the act af doing it often enough to believe that this act may be sometimes a part of the process by which we get an appreciation of space, which appreciation the writer believes is a sort of visual resultant dependent on no one thing for its characteristic sensations, and from which process almost any one factor may be eliminated without materially changing the result.

It having been proved by Dove that the rapid change of the images on the retina is not a necessary part of the stereoscope's function, it remains to study the images as they exist in an instant of time. This has been done by Helmholtz and others, and the results of their advance in physiological explanations are thought by some to demonstrate that the binocular perception is in the main dependent for its explanation on the phenomena which have been referred to, principally in this paper, in connection with the hand and the distant cross (Figs. 5140, and 5135 and 5136). Le Conte in 1871, and again in 1882, expresses his "own" view of the case as follows: "All objects or points of objects either beyond or nearer than the point of sight are doubled, but *differently*—the former homonymously, the latter heteronymously. The double images in the former case are united by *less* convergence, in the latter by *greater* convergence, of the optic axes. Now the observer knows, *instinctively and without trial*, in any case of double images, whether they will be united by greater or less convergence of the optic axes; in other words, the *eye* (or the mind) *instinctively distinguishes homonymous from heteronymous* images, referring the former to objects beyond, and the latter to objects on this side of, the point of sight. Or, again, in case of double images each eye, as it were, knows its own image, although such knowledge does not emerge into distinct consciousness. . . . This is all that is necessary for the perception of relief. But it is probable—nay, it is certain—that the relief is made clearer by a ranging of the point of sight back and forth, and by a successive combination of the different parts of the object, or scene, or pictures, as maintained by Brücke."

We have now followed the theoretical development of this interesting subject from the time of Alhazen to the present day. Most of the side issues have been for the time being completely ignored, but before proceeding to speak of one or two of those interesting questions, it will be wise for us to ask again, What is binocular vision, and on what, after all, does it depend for the important place which it has occupied in mental and ophthalmological literature.

That there is something worthy of a name and a class by itself cannot be doubted by anyone who has had the pleasure of looking through a stereoscope at some of the striking cards published by Dr. Green—for instance, that which was reduced to form Fig. 5144, in which the appearance of relief is so startling and unexpected that it would seem impossible, for anyone who had seen it stereoscopically, to notice anything about it so much as the change brought about by the fusing of the two pictures. To this plate, printed to illustrate how a single one of the conditions that contribute to our perception of relief may be sufficient to overbear any or all of the others, we come with entirely unprejudiced attention. The word Helmholtz on each side of the card is printed with what seems to be most ordinary type, that might have type, and I doubt not the same from the regular stock of some ordinary printing establishment; and anyone would expect, in looking into the stereoscope, to see something very like what is seen by either eye on either side, with perhaps a little blurring where the pictures do not quite coincide; but the first impression as the pictures are superimposed, whether by looking through a stereoscopic apparatus, or by diverging the optic axes, is that the whole word is not at all indistinct, but that it has tipped forward at least forty-five degrees, and while the bottom of the letters remains on the paper, the top of each letter is much this side of where it was before. The difference between the pictures as seen with either eye, and with two together, is so decided and so obtrusive that one does not feel justified in finding much fault with the assertion that it is principally through binocular vision that we get our most decided visual perceptions of the solidity of space. But it is quite certain that these perceptions are not entirely and always due to the binocular arrangement, and that they are not in all cases to be attributed to the same condition or combination of conditions.

Fig. 5141.

We have considered in turn each one of the methods by which it would be possible for a conscious thinking person—a person of intelligence—to judge of distance by carefully attending to the differences in the sensations that he is capable of receiving through the visual sense. We have seen that in our practical, every-day experience these sensations have varied in such a constant relation to the distance that, with perceptive faculties such as we are known to possess, we could arrive by logical processes at very definite and accurate estimations of space relations. We know that for untold ages our ancestors have had the ability to arrive at these definite conclusions in regard to position in this same way. We know also that the human mind is such that logical processes that are continually repeated, for definite purposes and with definite and unvarying results, cease to go on under the domain of consciousness, if they go on at all; but the results are reached with as great or greater accuracy than if they continued; and we know also that this ability that exists in some part of our brain to do routine work is at first the result of long individual experience, but that after a while it is in some measure transmitted, and may be considered as the property of the race—still the result of experience, though not necessarily of individual experience. We know that our ability to estimate depth is instantaneous, and we know that it is greater with two eyes than it is with one. Many of us have been taught to believe that the uniocular picture is a flat picture, but it is not, though under some circumstances one eye is not able to appreciate relief where two give easy and abundant evidence of it. It may not be that any of the more close students of the subject of binocular vision have believed that all our visual perceptions of depth were due to the binocular function; still it is very easy for one who reads on this subject to become possessed of that idea from what he reads.

The writer believes that the perception of depth in the binocular picture that presents itself to any adult who opens both eyes to see it is the result of experience gained either from his infancy or his ancestry, and that it may be, and sometimes is, the resultant of all the following impressions, viz.: That produced by

1. Parallax.
2. Focal perspective.
3. Aerial perspective.
4. Mathematical perspective and preconceived ideas and expectations.
5. Transparency of images or parts of images.
6. Incorrect superposition of images.
7. Doubling of images.
8. Change in binocular adjustments for different depths.
9. Ability to distinguish between homonymous and heteronymous diplopia.

The first four of the above conditions may exist in uniocular vision. The fifth may be either a uniocular or a binocular phenomenon. The last four can only be experienced by a person having two eyes. For 1 and 8 an appreciable amount of time is required; for all the others the perception may be instantaneous.

The writer believes also that the perception of relief may be, and often is, experienced through any one of these nine factors alone, or from two or more in combination, but that the uniocular sensations are as a rule much less vivid and impressive than the binocular; still they are important factors of the general resultant. For the perception of very great depth, where the interocular space may be considered as infinitely small compared with the distance, aerial perspective (3) is perhaps the most important and mathematical (4) next, though the effect of parallax voluntarily or accidentally obtained is in no way to be ignored. For all shorter distances the most vivid impressions of depth come from 2, 9, 5, and 4, and though the ability to distinguish between homonymous and crossed diplopia (9) may be considered the most important, it is sometimes entirely subordinated by mathematical perspective (4).

It is perhaps rather unusual to find all these elements working together for a single impression, but with all our looking and our constant motion there is hardly a moment of the day when we are not indebted for something to each one of them, except, of course, aerial perspective for in-door scenes.

It is also well known that these impressions, though very generally correct, are not always so. Exceptional cases occur in which either accident or design produces anomalous effects which, if single, are very likely to be deceptive; for example, a mist over one part of a landscape while the sun is over another will deceive us as to the relative distance unless there be some means of judging of it other than aerial perspective. On account of circumstances similar to these we may obtain through our eyes two different kinds of evidence in regard to depth, as when 4 and 9 are directly antagonistic in their evidence. These cases, though not so common in nature, are easily produced; and a very striking one is that referred to by Le Conte, in which the stereoscopic pictures of a street are mounted so as to produce, by the crossing of the images (6, 7, 8 and 9), just the opposite effect that is suggested by the aerial and mathematical perspective. In this case the prejudice is so great in favor of having the smaller objects measured by their angular size at the greater distance from us, and the ability to form mathematical judgments is so great that the entire binocular function seems to be ignored and it is impossible to be deceived, though according to the above classification 3 and 4 alone were opposed to 5, 6, 7, 8 and 9, while 1 and 2 were out of the argument. This is interesting as showing a strong evidence of what may be called uniocular stereoscopic vision.

As the eye in one twenty-four hundredth part of a second is capable of gathering in evidence of seven different kinds in regard to solidity and as in less than one-tenth of a second those two kinds that depend upon its rapid change of adjustment may be added, it is interesting to know what will be the result when there is not perfect agreement in the different kinds of data that are thus obtained. It would be natural to suppose that the resulting impression would be a kind of general average corresponding to the mechanical resultant in problems of physics. This is no doubt sometimes the case, but not always; or at least the resultant is so modified by or ments not purely visual that it cannot be called the visual resultant. In cases, for instance, where the mathematical and binocular perspective are directly opposed in their evidence, as in the one just quoted, it is impossible for us to believe that one of two objects is at the same time much nearer and much farther than the other, so the mind, as would be expected, decides on the relative validity of the two kinds of evidence and seems unhesitatingly and unconsciously to ignore the seemingly less reliable.

The hypotheses thus far treated of in a theoretical way concerning the causes of our stereoscopic sensations may be considered proved if, without the element of depth, we can reproduce the sensations at any time by reproducing the causes on which we believe them to depend and so isolated from other phenomena that there shall be no doubt of their constant connection with the sensations in question.

This is done most beautifully by the stereoscope, an instrument invented by Wheatstone for the purpose, and which in another form has since become a household article. The object of the stereoscope is to place at the same time before each eye a plane picture of some solid object or collection of solid objects; these pictures being nearly alike, but differing just as the retinal pictures would differ on account of the different positions of the two eyes. When such pictures are placed before the eyes and arranged in such a position that the directions of the visual axes and the focal adjustments of the eyes are the same as if they were looking at the real objects in space instead of the flat pictures of them, the results are so strikingly like the sensations produced by objects occupying three dimensions in space that they have only to be seen to be appreciated.

Wheatstone's instrument is not the one in common use, but is a reflecting instrument made by placing two mirrors together at an angle of nearly ninety degrees, as in Fig. 5145, the pictures being placed one on each side at l and r, and so reflected as to be seen as one solid picture when both eyes are directed to the point O. The effect, as everyone knows, is very striking. The same result would, of course, be obtained by placing each mirror at right angles to its present position and the pictures back to back between them. Sir David Brewster

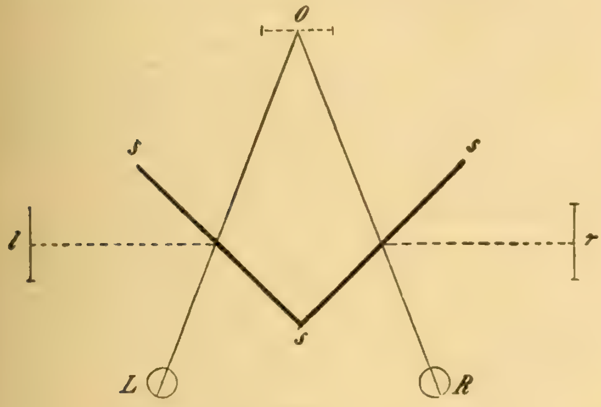

Fig. 5145.

was the inventor of the refracting stereoscope which, with slight modifications, is in use to-day. The older instruments were made like that pictured in Fig. 5146; the centre of each picture being placed directly in front of the corresponding eye, and before each eye, at P and P′, were prisms of such strength as to superimpose l and r at o. The screen s s prevented each eye from seeing the picture that belonged to the other. Each of the prisms in use at P and P′ was united with a convex lens, which was used principally for its magnifying effect, but which somewhat interfered with the sense of distance that would depend on the proper co-ordination of the convergence and the accommodation. In the stereoscopes that are most in use to-day this anomaly does not exist. The pictures are made so large that their centres are considerably outside of the axes of vision and the prisms are merely strong enough to bring the centres of the pictures so near together as to allow of their being seen when the visual axes are parallel, while the convexity of the lens is such as would correspond to the amount of accommodation that ought to be used to make distinct the picture at the distance at which it is really placed in the stereoscope. In this way the physiological condition of the eye in looking at a distant scene is exactly reproduced in looking at the plane pictures of the stereoscope, and the resulting deception is quite perfect. This latter form of stereoscope is seen in Fig. 5147.

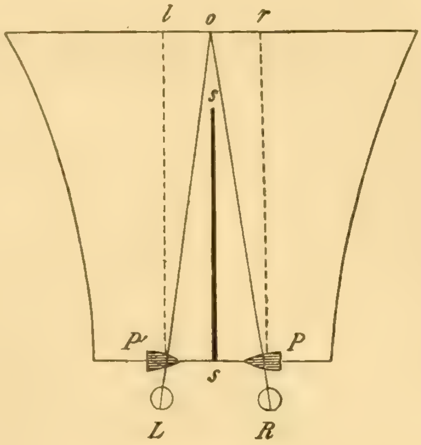

Fig. 5146.

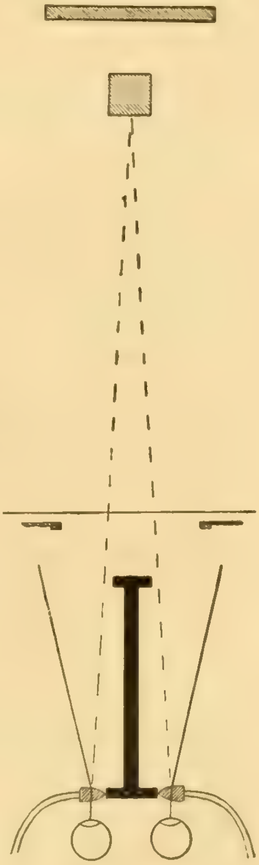

Fig. 5147.

Some of the stereoscopes in the shops to-day have no prisms at all in them, but are calculated to have the centre of each picture directly in front of the eye, while the lens is such as to supply the accommodation that would correspond to the distance at which the picture is really placed. The deception in this case is quite the same, the only disadvantage being in the limitation of the size of the picture in breadth to the interocular distance. There are other stereoscopes in which the superposition of the unlike images is brought about by different devices, but they all amount to the same thing and produce the same effects. One of the earlier forms was that invented by Dove (Fig. 5148), in which the displacement of the pictures is brought about by two right-angular convex prisms each producing two refractions and one total reflection.

Illustrative of the power of the stereoscope in giving the appearance of relief to plane figures, we may take the cut given by Gauss (Fig. 5149), which is the flat picture of a truncated pyramid with the smaller end directed toward the observer. The right-hand picture is the pyramid as it appears to the right eye, and the left is as it appears to the left eye. In the stereoscope neither eye can see the picture that is meant for the other. The prisms are arranged so that each picture falls on the most sensitive part of the retina when the eyes are in a position of rest, and the convex element in the prismatic glass makes the lines clear and distinct when the eye is focussed for distance. The result is that the two pictures fall as nearly on corresponding points as it is possible for two such different pictures to fall, and exactly the same effect is produced as if the eyes were looking at a truncated cone that was a great way off and that was large enough to fill up the same angular space that each picture fills. This gives the appearance of much greater size than can be attributed to the change brought about in the retinal image by the convex lens and it also gives the same appearance of solidity that would come from looking at a real one at the distance that would allow of its being seen with the axes practically parallel. Now if we look at this picture in the stereoscope we shall be able to see most of the phenomena that would have been presented if we were looking at the real cone in the position that this is supposed to occupy. We can even get the parallax in a slight degree by moving the head on account of the property which we recognize in the convex lens to displace eccentric pencils in a ratio that is increased with the eccentricity. We cannot, it is true, get the focal perspective, for the lens we use has practically a flat field, and the same accommodation, or lack of it, is needed for all parts of the picture; but as the visual axes are in this case parallel, the picture appears to be at a distance where focal adjustment is not an important factor in our estimation of depth. We have no aerial perspective, nor should we expect any, in a figure of no greater apparent depth than that is made to represent. There is nothing in it to oppose our ideas of mathematical perspective, and all the phenomena which give us a binocular perception of space-relations are fully represented. We have the imperfect superposition of images evident from the doubling that takes place in one part of the figure when we are looking at a part that is apparently more or less removed from us. We have the effect of transparency, or we should have, if the sides of the figure were shaded a little.

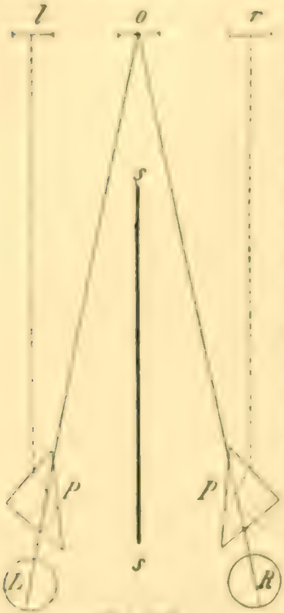

Fig. 5148.

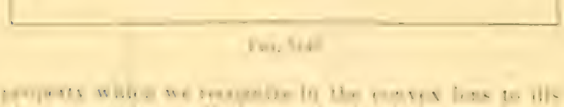

Fig. 5149.

If we transpose these pictures in Fig. 5149 the effect is obviously reversed, for the picture that is now seen by the right eye will then be such as would appear if we were looking into a hollow box instead of at a projecting pyramid, and the apparent central depth of the box will be just as striking as was the projecting centre of the pyramid. A stereoscope is not at all necessary to get these effects. A single prism held before one eye so as to displace both pictures enough for the right-hand picture as seen by one eye to fall on the left hand as seen by the other, will give precisely the same effect, only slightly modified by the fact that as we are obliged to use the accommodation the apparent distance will be a little decreased; and whether we see the picture of a pyramid or a box will depend on whether we hold the prism so as to displace the pictures inwardly or outwardly. Indeed, with a little practice no apparatus of any kind is necessary; we have but to diverge or converge the optic axes as we look, so that one eye points at one picture and the other eye at the other picture, and then wait a moment until the lens adjusts itself to the anomalous position, and we shall get the stereoscopic effect as vividly or nearly so, as if we had an instrument to aid in the illusion. Those who have difficulty in doing this will be aided if, when trying to make the axes diverge, they imagine themselves to be looking straight through the central point of the card at some imaginary point a long distance beyond; or, if this does not answer, it may be of greater help to look over the top of the card and fix the eyes on some real distant point when the images will be seen to double like those of the hand in a previous experiment.

It is very hard to fuse the modern stereoscopic pictures in this way, because the distance between the centres is usually greater than the interocular distance, and none of us have ever any need to diverge the eyes in actual life, and few of us are able to do so voluntarily; but any of the diagrams here printed as stereoscopic cards can be easily fused after a little practice, either by divergence or crossing, the relief in the one case being just the opposite of that in the other.

The experimenter may aid himself in crossing the eyes by holding the point of a pencil midway between the two pictures and fixing on that, and, while looking at it, withdraw it toward himself until the diplopia produced is just enough to place one picture over the other. In either of the last two cases the central picture will be the stereoscopic one, while on either side of that will be seen the two monocular pictures that are not visible in the stereoscope on account of the central screen.

As would be supposed, the stereoscope offers great advantages to the experimenter who is desirous of taking up, one at a time, the causes that tend to give the notion of solidity and testing their value as contrasted with other phenomena. Though something has been done in this line, the writer is not sure that anyone has attempted to go over the elements as classified above and make out a table in which each one should receive its comparative value in a quantitative as well as a qualitative way. This would be a most interesting thing to do, and would be another step among the many that are being taken nowadays toward making ours an exact science, and a comparatively easy step, too, for so much has already been done in detail that it seems as if only a little repetition and invention were necessary before the whole could be shaken together so that the different values of the elements and their combinations would be known.

There have been many experiments since the time of Brewster bearing on this point, but it seems now as if the time were ripe for the classifying and assigning definite values or, at least, relative values, and the stereoscope gives us many useful hints; e.g., in Fig. 5150, published by Dr. Green, after Brewster, the element of convergence alone, which is needed in a greater degree for the fusion of the right- than the left-hand image, produces very marked deception in regard to both size and distance of the two squares.

Before leaving the stereoscope, the telestereoscope ought to be mentioned. It is an instrument invented by Helmholtz for increasing our power to estimate distance by practically increasing the interocular space. This is done by the aid of four mirrors or reflecting surfaces, so arranged (Fig. 5150) that while the eyes look toward the object the pictures formed on the retina are such as would be there formed if the eyes were as far apart as the two outside mirrors.

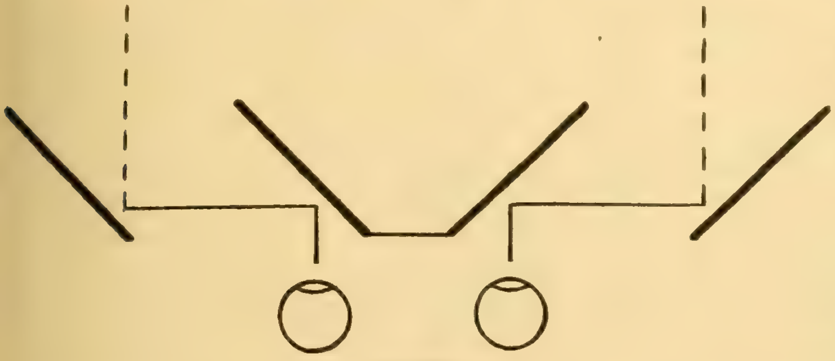

FIG. 5150.

The horopter is something that ought not to be trifled with by anyone who is not fond of pure mathematics. That there is such a thing no one will doubt, but it is much easier to define than to describe it. It is the locus of all those points in space that are at the same time so situated that their images on the two retinæ fall on corresponding points. To illustrate, let both eyes be directed, as in Fig. 5138, to the point A, the two visual axes in this case being represented by A a and A a′. Now any point, as B, so situated in space that the angle B D A is equal to the angle B S A, and of the same sense, will be so situated that its image will fall on corresponding points of the retinæ, and it will be seen single when both eyes are looking at A, and the sum of all the possible situations for such points, *i.e.*, what is known in geometry as the locus of a point subject to those conditions, is the horopter. Of course, the horopter changes for every change of the point of fixation.

When we begin to investigate the properties of the horopter our task seems as easy and as plain sailing as one of Euclid's propositions, and we soon obtain what is known as the horopteric circle of Mueller, given in Fig. 5138. This is that part of the horopter that cuts a horizontal plane passing through the eyes, and we see by it, or we seem to see by it, that all those points lying on the horizon that are seen single will be in a circle drawn through the nodal points of the eyes. This assertion depends upon the supposition that the vertical meridian in each eye remains vertical under all degrees of convergence, and upon the well-known geometrical truths that vertical angles are equal, that the sum of the internal angles of a triangle is equal to a constant quantity, and that inscribed angles subtended by the same chord are equal; from this we go on a step further, to develop this horopteric line into a horopteric surface by revolving it round the chord D S. The surface of revolution thus formed is known as a torus, a section of which is shown in Fig. 5151, and that part of it which is included in the field of vision is what would be the horopter if the conditions thus named held good. But the conditions do not hold good, for, as has been shown by Listing and others, the vertical meridians of the eyes do not remain vertical under convergence, and so the horopter above described is only correctly estimated for distances so great as to be practically infinite, and then the spherical surface that represents the horopter is a plane at infinity. It is hardly possible, in a short article like this, to follow all the researches that have been made on the actual shape of the horopter. The results of what has been done toward the determination of its true shape are thus summed up by Professor Le Conte:

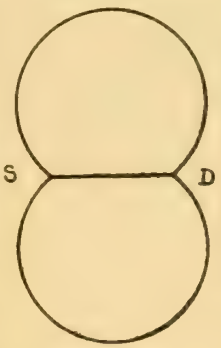

FIG. 5151.

"In regard to the horopter, I consider the following points to be well established. 1. As a necessary consequence of the outward rotation of the eyes in convergence for all distances in the primary visual plane, the horopter is a line inclined to the visual plane, the lower end nearer the observer. But whether the inclination is constant, or increases or decreases with distance, I have not been able to determine with certainty. It is probably constant.

"2. In depressing the visual plane the inclination of the horopteric line becomes less and less until, when the visual plane is inclined forty-five degrees below the primary position, the horopteric line becomes perpendicular to the visual plane and at the same time expands into a surface. The exact nature of the surface I have not attempted to investigate, but it is evidently a curved surface.

"3. In elevating the visual plane, especially with strong convergence, the inclination of the horopteric line increases."

Before leaving the horopter in this very unfinished state, it is interesting to note that the shape of the horopter has been suggested as having something to do with our usual impression in regard to the shape of the sky, which seems to form a concave surface over our heads. It seems rather doubtful whether this is the case.

The horopter has also, like so many of the binocular phenomena, a faint foreshadowing in the uniocular field: thus in Fig. 5133 the points A, B, and C may be taken as illustrative of the fact that the eye has not a flat field, and that each one of the many points marked on the retina must have somewhere in space a conjugate focus and those in the periphery of the field will be farther from the eye than those directly in front. The exact position cannot be definitely stated on account of the astigmatism of eccentric pencils; but this would seem to be of little importance, because of the comparative insensibility of the periphery of the retina, and because of our habit of turning the eye toward anything that we wish to see distinctly. In the same way, it does not seem to matter much in every-day affairs where the horopter goes to after it has passed out very far from the central field, but it is necessary to know something of the position of its uniocular prototype in making experiments for the determination of the relative visual acuteness of the different parts of the retina.

The writer is obliged to pass over, with only very brief mention, a number of beautiful diagrams published by Professor Le Conte in his book on sight, illustrative of the fact that we do not seem to see objects as with two separate eyes, one of which is in one position and one in another; but we have apparently only one visual field, and, as we look out into the world, we seem to be looking as if out of a single eye to be fixed midway between the two that we really use. In these diagrams we have a representation of what each eye really sees, and, besides this, of the object as it appears to us after being transferred by the mind to its true position as regards ourselves, i.e., to the place that it seems to occupy relative to an imaginary eye in the middle of the interocular space.

A word or two ought to be said in regard to the importance of a comparatively poor eye to the binocular combination.

As has been before remarked, two eyes do not see a plane surface where there is no perspective or relief very much better than one, but it is surprising how much a very poor eye will add to the ability to judge of distance. The lens of the organ may be wanting entirely, and the cornea be somewhat clouded with opacities, and yet the eye have the ability to direct itself with considerable precision; and as long as that is the case, great help will be given to the judgment of distance, as might be supposed from the importance that convergence plays in making up the estimation (see Fig. 5141, illustrative of this point). This is not only useful to the patient in many every-day affairs, such as judging of the height of a step, but, besides this, the pertinacity that is shown in many patients who have eyes that can in no way form images on the retinæ nearly enough alike to admit of their being fused in the ordinary acceptation of the term—the pertinacity that is shown by them in continuing to use both eyes together, instead of ignoring one and letting it turn out or up when some kind of trouble makes it much easier for them to do this, is quite significant of the amount of help that can be got from a comparatively poor organ. The writer cannot close this paper without expressing his sincere thanks to Dr. John Green, of St. Louis, for the very material aid that he has given, and his sorrow that the hurried manner in which it has been written makes it so little apparent that he has had the advantage of that help, and also of the very excellent book on the subject written by Professor Le Conte, of which he has made considerable use, though less than he would have made had time and space permitted.

W. S. Dennett.

VITILIGO. This affection of the skin, which is likewise known by the name of leucoderma, consists in the development of whitened areas upon various portions of the body, but especially of the face, neck, and hands. It is due to localized loss of pigment in rounded or ovoid patches of various size, having sharply defined margins and surrounded by more or less deeply pigmented skin which gradually shades off into the normal. The characteristic features of the whitened spots are that their border is usually convex, giving the impression that they extend into their darkened surroundings, or in their advance drive the pigment before them; that there is no change in the structure, sensations, or secretions of the affected areas; and that their tendency is to persist and to increase in extent, being little affected by any treatment. It is an acquired condition coming on usually in youth or early adult life without previous ill-health or prodromata, though in some instances it has been known to follow local injury and sometimes develops in the neighborhood of a pigmented mole. The dark-skinned races are rather more subject to vitiligo than those of fair skin and light hair, and it is not so very rarely seen in the negroes of this country, in whom the contrast between the perfectly white spots and the normal skin produces a striking effect. I have seen instances where much discomfort of mind was occasioned by the fact that the white patches were merging into each other until extensive regions of the body had lost their pigment, and the negro was fearful that he was "turning into a white man." The hair may lose its pigment in the same way as the skin, and rounded or irregular tufts of gray may appear upon the head. In white races the affected regions are often more noticeable in the summer time, when the surrounding pigmentation becomes deeper.

The *diagnosis* of vitiligo is not difficult, although it is liable to be confounded with morphœa, chloasma, tinea versicolor, syphilitic pigmentations, macular leprosy, and albinismus. One chief point by which it is distinguished from other conditions is the normal condition of the skin, apart from its loss of pigment. In morphœa there are structural changes. In tinea versicolor the patches are inflammatory and scaly, and from them scales can be scraped which show, under the microscope, the characteristic groups of spores, although when circumscribed areas of healthy white skin are enclosed in the brownish patches of this disease, vitiligo may be closely simulated; but the margins will be found irregular instead of clean-cut. In chloasma there is increased pigmentation of the patch itself and the circumference is the part which appears white. The distinction has been made that in vitiligo the margin of the white area is convex toward that which is pigmented while in chloasma it is concave, but in some instances the patches run together in such a way that this becomes more theoretical than apparent. Syphilitic pigmentations, especially about the neck in women, may persist after other manifestations have disappeared and simulate vitiligo. In the macular form of lepra the patches of white skin have an irregular outline, not so abrupt as in vitiligo, and the tinge is rather grayish than dead white; then, too, the skin is either thickened or atrophied and anæsthesia or impaired sensation is present. Finally, in albinism we have, as in vitiligo, an absence of normal pigment, but in the former it is a congenital defect and the whole surface of the body, including the hair and eyes, may be devoid of pigment.

The *etiology* of vitiligo is not well understood, but the cause of the condition is usually ascribed to perverted innervation. It is probable that the disappearance of the pigment from one spot and its increased deposit in a neighboring part is due to an atrophy and hypertrophy in the respective regions brought about through the sympathetic nerve system. Sometimes, though rarely, the proper proportion of pigmentation is spontaneously restored, but in the majority of instances the affected areas tend to increase, and the condition to assume marked chronicity. When large extents of surface are involved the term leucoderma becomes appropriate.

The *treatment* is unsatisfactory. Some reports of success from electricity have been made. Local applications for the removal of surrounding pigmentation are resorted to with the view of rendering the white regions less noticeable. Internally, nerve tonics, especially strychnia and arsenic, are advised. Blistering the patches to excite a deposit of pigment has been tried, but the results are not brilliant. If upon the face or other exposed part, artificial staining may be employed, and dyes used to restore the color of the hair.

Charles W. Allen.

GENERAL INDEX.

Explanation of Signs.—The Roman numerals refer to the volume, the Arabic to the page. An asterisk (*) indicates that the subject referred to is treated at length in a separate article. (Fig.) following a reference shows that the subject is further explained by wood-cuts.

- helicis minor, i. 444
- hepatico-diaphragmaticus, v. 53
- hernia of, v. 55
- hyaline degeneration of, v. 58
- hyo-fascialis, v. 38
- hyo-glossus, anomalies of, v. 39
- hyo-maxillaris, v. 39
- hyo-pharyngeus, v. 632
- hyperæsthesia of, v. 58
- hypertrophy of, v. 57
- iliacus, anomalies of, v. 49

Muscle or muscles (continued):
  iliacus minor, v. 49
  ilio-capsularis, v. 49
  incisuræ Santorini, i. 444
  infarctions in, v. 55
  inferior constrictor of pharynx, anomalies of, v. 40
  inflammation of, v. 55
  influence of the tobacco habit upon, viii. 553
  infra-spinatus, anomalies of, v. 44
  injuries of, v. 54
  inspiratory, ii. 212 (Fig.); vi. 206
  internal intercostal, anomalies of, v. 53
  internal oblique, i. 11
  interosseous, of the foot, v. 52
    of the hand, anomalies of, v. 48
  interspinales, anomalies of, v. 53
  intrinsic, of the auricle, i. 444
  ischio-calcaneus, v. 48
  ischio-cavernosus, anomalies of, v. 54
  ischio-condyloid, v. 49
  ischio-femoral, v. 48
  laryngo-pharyngeus, v. 631
  lateralis abdominis, v. 53
  latissimus dorsi, anomalies of, v. 40 (Fig.)
  levater anguli scapulæ, anomalies of, v. 41 (Fig.)
  levator claviculæ, v. 41
  levator labii superioris proprius, anomalies of, v. 35
  levator palati, v. 633
  levator palpebræ, anomalies of, v. 36
  levator pharyngis, v. 632
  levator thyroideæ, v. 38 (Fig.)
  ligamentum nuchæ replaced by, v. 52
  longissimus dorsi, anomalies of, v. 52
  longus colli, anomalies of, v. 40
  lumbricales, anomalies of, v. 46
  lumbricales pedis, anomalies of, v. 51
  malignant tumors of, v. 58
  masseter, anomalies of, v. 36
  mento-hyoid, v. 39 (Fig.)
  middle constrictor of pharynx, anomalies of, v. 40
  multifidus spiræ, anomalies of, v. 52
  mylo-hyoid, anomalies of, v. 39
  myo-glossus, v. 40
  obliquus auriculæ, i. 444
  obliquus externus abdominis, anomalies of, v. 53
  obliquus internus abdominis, anomalies of, v. 53
  obturator externus, anomalies of, v. 48
  obturator internus, anomalies of, v. 48
  occipitalis, anomalies of, v. 35
  occipitalis minor, v. 36
  occipito-hyoid, v. 39
  occipito-pharyngeus, v. 40
  occipito-scapularis, v. 41
  of animal life, v. 59
  of Guthrie, iii. 37
  of mastication, ii. 449
    anomalies of, v. 36 (Fig.)
  of the auricle, i. 444
  of the face, iii. 7 (Fig.)
  of the foot, iii. 213 (Fig.)
  of the hand, iii. 490 (Fig.)
  of the new-born, iv. 10

Muscle or muscles (continued):
  of the perineum, v. 589
  of the skin, viii. 463
  of the soft palate, vii. 502
  of the thigh, adductor group, viii. 541 (Fig.)
    posterior group, viii. 545 (Fig.)
  omo-hyoid, anomalies of, v. 38 (Fig.)
  opponens hallucis, v. 52
  opponens minimi digiti, anomalies of, v. 48
  opponens minimi digiti pedis, v. 52
  osseous growths in, v. 387
  ossification of, v. 56
  pain in, v. 55
    in trichinosis, vii. 794
  painful contractions of, ii. 319
  palato-glossus, v. 634
  palato-pharyngeus, v. 633
  palmaris brevis, anomalies of, v. 47
  palmaris longus, anomalies of, v. 46
  parasites of, v. 59
  parenchymatous inflammation of, v. 56
  pectineus, viii. 541 (Fig.)
    anomalies of, v. 49
    tenotomy of, vi. 777
  pectoralis major, anomalies of, v. 41 (Fig.)
  pectoralis minimus, v. 43
  pectoralis minor, anomalies of, v. 42 (Fig.)
  peroneo-calcaneus internus, v. 51
  peroneo-tibialis, v. 51
  peroneus accessorius, v. 50
  peroneus brevis, anomalies of, v. 50
    tenotomy of, vi. 777
  peroneus longus, iv. 471 (Fig.)
    anomalies of, v. 50
    tenotomy of, vi. 777
  peroneus quartus, v. 50
  peroneus quinti digiti, v. 50
  peroneus tertius, anomalies of, v. 50
  petro-pharyngeus, v. 40
  petro-salpingo-staphylinus, ii. 730; v. 633
  pigmentary degeneration of, v. 58
  pisi-uncinatus, v. 48
  plantaris, iv. 473 (Fig.)
    anomalies of, v. 50
  platysma myoides, anomalies of, v. 36
  popliteus, iv. 473
    anomalies of, v. 50 (Fig.)
  popliteus minor, v. 51
  presternal, v. 42 (Fig.)
  prevertebral, anomalies of, v. 40
  primitive sheath of, v. 63
  pronator pedis, v. 51
  pronator quadratus, anomalies of, v. 46 (Fig.)
  pronator radii teres, anomalies of, v. 45
  psoas magnus, anomalies of, v. 48
  psoas parvus, anomalies of, v. 49
  pterygoideus externus, anomalies of, v. 36
  pterygoideus proprius, anomalies of, v. 36 (Fig.)
  pterygo-pharyngeus, v. 40
  pterygo-spinosus, v. 36
  pyramidalis, anomalies of, v. 53
  pyriformis, anomalies of, v. 48
  quadratus femoris, anomalies of, v. 48
  quadratus lumborum, anomalies of, v. 53

Muscle or muscles (continued):
  quadriceps extensor femoris, anomalies of, v. 49
    tenotomy of, vi. 777
  quadrigeminus capitis, v. 36
  radio-carpus, v. 46
  rectus abdominis, i. 11
    anomalies of, v. 53
  rectus capitis anticus major, anomalies of, v. 40
  rectus capitis anticus minor, v. 40
  rectus externus, anomalies of, v. 36
  rectus femoris, viii. 540 (Fig.)
  rectus sternalis, v. 42 (Fig.)
  rectus thoracis, v. 53
  red and pale, v. 71
  respiratory, ii. 312 (Fig.)
  retractores uteri, v. 549, 606
  retrahens auriculam, i. 444
  rheumatic inflammation of, v. 56
  rhombo-atloid, v. 41, 52
  rhomboideus minor and major, anomalies of, v. 41
  rhombo-occipital, v. 41
  risorius, anomalies of, v. 36
  rupture of, v. 54
  sacro-coccygeus anticus, v. 53
  sacro-coccygeus posticus, v. 52
  sacro-lumbalis, anomalies of, v. 52
  sartorius, viii. 540 (Fig.)
    anomalies of, v. 49
    tenotomy of, vi. 777
  scalenus anticus, anomalies of, v. 40
  scalenus medius, anomalies of, v. 40
  scalenus minimus, v. 40
  scalenus posticus, anomalies of, v. 40
  scansorius, v. 48
  scapulo-costalis minor, v. 43 (Fig.)
  semimembranosus, viii. 545 (Fig.)
    anomalies of, v. 48
  semitendinosus, viii. 545 (Fig.)
    anomalies of, v. 48
  serratus magnus, anomalies of, v. 43
  serratus posticus inferior, anomalies of, 52
  serratus posticus superior, anomalies of, v. 52
  shot wounds of, viii. 12
  signs of death in the, ii. 388
  skeletal, v. 59
  smooth, v. 68 (Fig.). See also *Muscular tissue, unstriated.*
  soleus, iv. 472
    anomalies of, v. 50
  spasmodic disorders of, ii. 286
  spheno-pharyngeus, v. 40
  spheno-salpingo-staphylinus, ii. 730; v. 633
  sphincter ani, anomalies of, v. 53 (Fig.)
  sphincter, of the pupil, iv. 218
  spinal, concerned in expiration, ii. 313 (Fig.)
  spinalis cervicis, anomalies of, v. 52
  spinalis dorsi, anomalies of, v. 52
  splenius accessorius, v. 52
  splenius, anomalies of, v. 52
  sternalis, v. 42 (Fig.)
  sterno-chondro-scapular, v. 43 (Fig.)
  sterno-clavicularis anterior, v. 43
  sterno-cleido-mastoid, anomalies of, v. 36
    tenotomy of, vi. 776
  sterno-fascialis, v. 37
  sterno-hyoid, anomalies of, v. 37
  sterno-scapular, v. 43 (Fig.)
  sterno-thyroid, anomalies of, v. 37

Muscle or muscles (continued).
  striated, v. 59
  stylo-auricularis, v. 40
  stylo-chondro-hyoid, v. 39
  stylo-glossus, anomalies of, v. 39 (Fig.)
  stylo-hyoid, anomalies of, v. 39
  stylo-hyoideus alter, v. 39
  stylo-pharyngo-thyroideus, v. 39
  stylo-maxillaris, v. 39
  stylo-pharyngeus, v. 632
    anomalies of, v. 40
  subanconeus, v. 45
  subclavius, anomalies of, v. 43
  subclavius posticus, v. 43 (Fig.)
  subcrureus, anomalies of, v. 49
  subcutaneous injuries of, v. 54
  subscapularis, anomalies of, v. 44
  subscapularis minor, v. 44
  subscapulo-capsularis, v. 44
  superficial flexors, anomalies of, v. 49 (Fig.)
  superficial transversus pedis, v. 52
  superior constrictor of the pharynx, anomalies of, v. 40
  supernumerary, v. 35 (Fig.)
  supinator brevis, anomalies of, v. 47
  supinator longus, v. 46
  supra-clavicular, v. 37
  supra-costalis, v. 53
  supra-spinatus, anomalies of, v. 43 (Fig.)
  syphilitic disease of the, vi. 729
  temporal, anomalies of, v. 36
  temporalis minor, v. 36
  tensor fasciæ plantaris, v. 50
  tensor palati, v. 633
  tensor trochleæ, v. 36
  tensor vaginæ femoris, viii. 540 (Fig.)
    anomalies of, v. 48
    tenotomy of, vi. 777
  teres major, anomalies of, v. 44
  teres minor, anomalies of, v. 44
  thyro-arytenoid, iv. 390 (Fig.)
  thyro-epiglottic, iv. 390 (Fig.)
  thyro-hyoideus, anomalies of, v. 38
  tibialis anticus, anomalies of, v. 49
    tenotomy of, vi. 777
  tibialis posticus, anomalies of, v. 51
    tenotomy of, vi. 777
  tibialis secundus, v. 51
  tibio-accessorius, v. 51
  tibio-astragalus anticus, v. 49
  tibio-fascialis anticus, v. 49
  tragicus, i. 444
  transversalis abdominis, i. 11
    anomalies of, v. 53
  transversalis cervicis anticus, v. 40
  transversalis cervicis medius, v. 40
  transversus auriculæ, i. 444
  transversus menti, v. 36
  transversus nuchæ, v. 37 (Fig.)
  transversus orbitæ, v. 36
  transversus pedis, anomalies of, v. 52
  transversus perinæi, anomalies of, v. 54
  trapezius, anomalies of, v. 40
    tenotomy of, vi. 776
  tremors of, v. 58
  triangularis menti, anomalies of, v. 36
  triangularis sterni, anomalies of, v. 53
  triceps, i. 308
  triceps extensor cubiti, anomalies of, v. 45

Muscle or muscles (continued).
  triticeo-glossus, v. 39
  tubercular inflammation of, v. 57
  tumors of, v. 58
  ulceration of, v. 55
  ulnaris quinti, v. 47
  ulno-carpeus, v. 46
  used in writing, vi. 33
  vascular tumors of, v. 59.

  regeneration of, v. 142*, 146
  renal splanchnic, viii. 510
  resection of, in facial neuralgia, iii. 20
  rôle of trophic, in the production of bed-sores, ii. 394
  second, ii. 324
  seventh, ii. 327
  sciatic, viii. 545 (Fig.)
  sensitive, termination of, v. 149
  sheath of Henle, v. 145
  sheath of Mauthner, v. 143
  sheath of Schwann, v. 144
  shot injuries of, viii. 16
  sinu-vertebralis, viii. 507 (Fig.)
  sixth, ii. 325
  small sciatic, viii. 544
  spheno-ethmoidal, ii. 326
  spheno-palatine, ii. 326
  spinal, vi. 592 (Fig.); viii. 477
  spinal accessory, ii. 331
    nidus of, viii. 182

Nerve or nerves, spinal accessory (continued):
    surface marking of, v. 112
  splanchnic, viii. 510 (Fig.)
    minor, viii. 510
  stimulation of, v. 139
  stretching of, v. 156; vii. 37, 122
  superficial cervical, surface marking of, v. 112 (Fig.)
  superficial, of the thigh, viii. 538 (Fig.)
  superior dental branches of spheno-palatine, ii. 326
  superior laryngeal, ii. 330
  superior maxillary, ii. 326 (Fig.)
  superior mesenteric, iv. 747
  supra-acromial, surface marking of, v. 112
  supra-clavicular, surface marking of, v. 112
  supra-orbital, ii. 326 (Fig.)
  supra-sternal, surface marking of, v. 112
  supra-trochlear, ii. 326 (Fig.)
  sympathetic system, viii. 505* (Fig.)
  tactile cells and corpuscles, v. 149 (Fig.); viii. 467 (Fig.)
  temporo-facial, ii. 328
  temporo-malar, ii. 326
  tensor tympani, ii. 327
  tenth, ii. 329
    nidus of the, viii. 181
  terminations of, v. 148 (Fig.)
    in ligaments, i. 373
    in the skin, viii. 467 (Fig.)
  third, ii. 325
    nidus of, viii. 179
  tonsillar, ii. 329
  trifacial, ii. 325 (Fig.); vii. 249 (Fig.)
  trigeminus, ii. 325 (Fig.); vii. 249 (Fig.)
    nidi of the, viii. 180
    raphé root of the, viii. 181
  trisplanchnic, viii. 506 (Fig.)
  twelfth cranial, ii. 331; iii. 796 (Fig.)
  tympanic, ii. 329
  ulnar, in the arm, i. 308
    in the forearm, i. 312
    in the hand, i. 317
    in the wrist, i. 313
  vagus, ii. 329 (Fig.)
  vaso-motor, i. 564
  Vater's corpuscles, v. 150; viii. 467
  velocity of impulse in, v. 137
  Vidian, ii. 328
  vital conditions of, v. 141
  Wagner's corpuscles, v. 149
Nerve-cells, v. 146 (Fig.)
Nerve-endings, v. 148 (Fig.)
  in the skin, viii. 467 (Fig.)
  special, in ligaments, i. 373
Nerve-fibres, v. 143 (Fig.)
  development of, v. 146
  division of, v. 145
  measurements of, v. 144
  non-medullated, v. 144
  of Remak, v. 144
Nerve-stretching in neuralgia, v. 156
  in tetanus, vii. 37
  lingual nerve, vii. 122
Nerve-supply of the groin, iii. 388 (Fig.)
  of the hip-joint, iii. 652
  of the shoulder-joint, vi. 447
Nerve-tissue, v. 143* (Fig.)
  chemistry of, v. 150

Nerve-tissue (continued):
  forms of, composing the brain, viii. 164
Nervi, v. 151*
Nervous actions, automatic and reflex, v. 152
Nervous affections due to phimosis, v. 640
  disqualifying for enlistment, ii. 742

Post-partum changes in the uterus, viii. 572
Post-partum hæmorrhage, iv. 347 ; vi. 73
  compression of the abdominal aorta in, i. 358
Post-partum regeneration of mucosa uteri, ii. 393 (Fig.)
Post-partum shock, vi. 70
Postpeduncle, viii. 128 (Fig.)
Postperforant vein, viii. 238
Postramus of arbor, viii. 127 (Fig.)
Postsemilunar lobe of cerebellum, viii. 126 (Fig.)
Posture, diagnostic significance of, v. 684
  in the treatment of retroversion of the uterus, vii. 452 (Fig.)
Postvermis of cerebellum, viii. 127 (Fig.)
Potain's aspirator, i. 389 (Fig.)
  mixer for blood-counting, iii. 687 (Fig.)
Potash, caustic, ii. 5 ; v. 793
  germicidal action of, iii. 326
Potassa, v. 793
  cum calce (Vienna paste), ii. 5 ; v. 793
  sulphurated, vi. 681
Potassic acetate, v. 794
  arsenite, i. 343
  boro-tartrate, v. 795
  carbonate, acid, v. 793
    normal, v. 793
  chlorate, v. 796
  citrate, normal, v. 794
  cyanide, ii. 350
  hydroxide, v. 793
  iodide, iv. 203
  nitrate, v. 795
  nitrite, v. 190
  permanganate, iv. 638
  tartrate, acid, v. 795
    normal, v. 795
  sulphate, normal, v. 795
  sulphite, normal, vi. 682
Potassio-ferric tartrate, iv. 227
Potassio-sodic tartrate, v. 794
Potassio-sulphate of aluminium, i. 126
Potassium, v. 792*
  acetate, v. 794
    germicidal action of, iii. 326
  and sodium tartrate, iv. 459 ; vi. 102
    as a cholagogue, ii. 110
  arsenite, antiseptic efficacy of, i. 255
    germicidal action of, iii. 326
  bicarbonate, v. 793
  bichromate, ii. 154
    antiseptic efficacy of, i. 254
    germicidal action of, iii. 326
  binoxalate, v. 441
  bitartrate, v. 795 ; vi. 102
  bromide, i. 697
    as a motor depressant, v. 27
    as an emmenagogue, ii. 678
  carbonate, v. 793
    antidotal value of, i. 242
Potassium (continued):
  chlorate, v. 796
    germicidal action of, iii. 326
    poisoning by, v. 796
  chromate, germicidal action of, iii. 326
  citrate, v. 794
    diaphoretic action of, ii. 425
  cyanide, ii. 350
    antiseptic efficacy of, i. 254
    disposition of, in the body after absorption, v. 765
  ethylate, use of, as a caustic, ii. 6
  ferrocyanide, antidotal value of, i. 243
  general medicinal properties of compounds of, v. 792
  hypophosphite, iii. 799
  indoxylsulphate, v. 262 ; vii. 416
  in urine, vii. 420
  iodide, iv. 203
    antiseptic efficacy of, i. 255
    germicidal action of, iii. 326
  iodohydrargyrate of, iv. 742
  medicinally used compounds of, v. 792
  myronate, v. 76
  nitrate, v. 795
    germicidal action of, iii. 326
    poisoning by, v. 796
  nitrite, v. 190
  permanganate, antidotal action of, to crotalus venom, viii. 450
    antiseptic efficacy of, i. 254
    as a deodorant, ii. 406
    as an emmenagogue, ii. 677
    germicidal action of, iii. 326
    in antiseptic surgery, i. 264
    poisoning by, iv. 639
  salts, diuretic action of, ii. 522
  skataxyl sulphate, vii. 415
  sulphate, v. 795
  sulphite, vi. 682
  tartrate, v. 795
  tartrate of iron and, iv. 227
Potato, i. 486
  starch of, vi. 618 (Fig.)
  sweet, iv. 236
Potato-cultures, iv. 771 (Fig.)
Potato-paste as a culture medium, iv. 772
Potential cauteries, ii. 4
Potentilla sylvestris, vi. 152
Potter, William Henry, on teeth, vi. 741
Potters, diseases of, v. 280

  detection of, in drinking-water, vii. 702
Urine (continued) :
  dextrose in, vii. 428
  earthy phosphates in, vii. 418
  echinococcus hooks in, vii. 441
  eggs of distoma hæmatobium in, vii. 441
  entozoa in, vii. 441
  epithelium in the, iv. 797 (Fig.) ; vii. 439 ; viii. 557 (Fig.)
  estimation of urea in, vii. 410
    of uric acid in, vii. 413
  examination of, in pyelitis, viii. 557 (Fig.)
  excretion of, effects of exercise upon, ii. 758
  extravasation of, vii. 402
    anatomical study of course pursued in, i. 10
  fat in, vii. 434
  fatty acids and their derivations in, vii. 415
  fibrin in, vii. 421
  fruit-sugar in, vii. 428
  fungi in the, iv. 800 (Fig.)
  general characteristics of, vii. 403
  glucose in, vii. 428
  glycerine phosphate in, vii. 418
  gonococcus in, vii. 440
  gonorrhœal thread in the, vii. 405
  grape-sugar in, vii. 428
  hæmoglobin in, vii. 421, 427
  hemi-albuminose in, vii. 426
  hemipeptone in, vii. 421
  history of analysis of, vii. 403
  hypoxanthin in, vii. 414
  incontinence of, ii. 697 ; iv. 810
    excited by the noise of bagpipes, iv. 2
  indogen in, vii. 416
  indol in, vii. 415
  infiltration of scrotum by, iii. 308
  inorganic constituents of, vii. 417
  inosite in, vii. 428
  iron in, vii. 421
  lactic acid in, vii. 415
  lactose in, vii. 428
  lardacein in, vii. 421
  larval forms of filaria sanguinis hominis in, vii. 441
  leucin in, vii. 435
  levulose in, vii. 428
  lymphous, vii. 435
  magnesium in, vii. 420
  metals found in, vii. 420
  methæmoglobin in, vii. 427
  microscopical examination of, iv. 797 (Fig.)
  milk-sugar in, vii. 428
  mucin in, vii. 421
  muscle-sugar in, vii. 428
  nitrogenous bodies excreted in the, v. 257
  normal acidity of the, i. 59
  normal constituents of, vii. 409
  normal pigment of, vii. 416
  odor of, vii. 405
  oxalate of lime sediment, vii. 438
  oxalic acid in, vii. 415
  oxaluric acid in, vii. 415
  oxyhæmoglobin in, vii. 426
  paraglobulin in, vii. 421
  parapeptone in, vii. 421
  peptone in, vii. 421
  phenol in, vii. 415
  phosphates in, vii. 418
  phosphoric acid in, vii. 418
  potassium in, vii. 420
  preservation of, vii. 441
  propeptone in, vii. 421

Urine (continued):
  pus in the, iv. 798 (Fig.), 812; vii. 439
  pyrocatechin in, vii. 415
  quantity of, vii. 404
  reaction of, vii. 407
  remedies to increase secretion of, ii. 620
  retention of, after circumcision, ii. 174
    aspiration in, i. 390
    dystocia from, iv. 340
    from stricture, treatment, vii. 402
    in cystitis, i. 512
  saccharine, ii. 416
  saccharomyces urinæ, vii. 440
  sarcin in, vii. 414
  scatol in, vii. 415
  schizomycetes in, vii. 440
  secretion of, iv. 271; vi. 377
    conditions which modify, in health and in disease, ii. 529
    effects of fasting upon, iii. 40
    in childhood, ii. 94
    in the new-born, iv. 11
  sediments in, iv. 797 (Fig.), vii. 436
    preservation of, vii. 441
  serum-albumen in, vii. 421
  serum-globulin in, vii. 421
  sodium in, vii. 420
  sodium chloride in, vii. 417
  solids of the, vii. 406
  specific gravity of, vii. 406
  spectrum of, vi. 520 (Fig.)
  spermatozoids in, vii. 440
  succinic acid in, vii. 415
  sugar in, vii. 428
    clinical significance of, vii. 432
    tests for, vii. 429
  sulphates in, vii. 419
  sulphur compounds in the, v. 262
  sulphuric acid in, vii. 419
  suppression of, in a case of chlorosis, ii. 107
  syntonin in, vii. 421
  tailed cells in the, not diagnostic of pyelitis, viii. 558
  tests for albumen, vii. 421
    sugar, vii. 429
  transparency of, vii. 405
  triple phosphate deposit in, vii. 438
  tubercle-bacillus in, vii. 440
  tyrosin in, vii. 435
  urates in, vii. 437
  uric acid deposit in, vii. 436
  urobilin in, vii. 416
  urochrome in, vii. 416
  uroglaucin in, vii. 417
  uroxanthin in, vii. 416
  urrhodin in, vii. 417
  variations in quantity of, in hysteria, iii. 809
  xanthin group of organic bodies in, vii. 413
  xanthin in, vii. 414
  yeast fungus in, vii. 440
Urine indican, vii. 416
Urinometers, vii. 406 (Fig.)
Urobilin, i. 499; vii. 416
Urochrome, vii. 416
Urocyst. See *Bladder*.
Urogenital ducts derived from cœlom, ii. 223
Urogenital fold, development of the, iii. 178 (Fig.)
Uroglaucin, vii. 417
Urostealith, calculi of, ii. 259
Uroxanthin, vii. 416
Urrhodin, vii. 417
Ursone, i. 482
Urticaria, vii. 441*
  and eczema, differential diagnosis of, ii. 634
  bullosa, vii. 441
  causes, vii. 442
  diagnosis, vii. 442
  feigned, iii. 60
  giant, vii. 441
  hæmorrhagica, vii. 441
  papulosa, vii. 441
  pathology, vii. 442
  pigmentosa, vii. 442*
  treatment, vii. 442
  tuberosa, vii. 441
Ustilago, vii. 442*
  maïdis or maydis, ii. 301, 717; iii. 265; vii. 442
Uterine dilators, vii. 448, 478 (Fig.)
  repositor, vii. 453 (Fig.)
  supporter, Banning's, v. 372 (Fig.). See also *Pessaries*.
Uterus, absence of the, vii. 463
  adenoma of, vii. 496 (Fig.)
  anatomy of, vii. 563 (Fig.)
  and adnexa, diseases of, water treatment of, i. 464
  anteflexion of, vii. 447
  anteversion of, vii. 446
    pessaries for, v. 617 (Fig.)
  anvil-shaped, vii. 468 (Fig.)
  arbor vitæ, vii. 566
  bicornis, vii. 467 (Fig.)
  biforis, vii. 473 (Fig.)
  bilocularis, vii. 469 (Fig.)
  broad ligament, vii. 564
  carcinoma of, i. 23; vii. 497 (Fig.); viii. 561
    amputation of cervix in, vii. 498
    diagnosis, vii. 498
    duration, vii. 498
    etiology, vii. 497
    extirpation of, vii. 499
    prognosis, vii. 498
    result of operation for, vii. 499
    symptoms, vii. 498
    treatment, vii. 498
  cauliflower excrescence of, i. 775 (Fig.)
  cavity of, vii. 565
  cervical sympathetic ganglion, viii. 512
  cervix, vii. 566
    abnormal plication in cavity of the, vii. 473 (Fig.)
    abrasions of, vii. 477
    absence or atrophy of, vii. 465
    amputation of, vii. 476, 499 (Fig.)
    atrophy, vii. 473
    carcinoma of, vii. 497; viii. 561
    chancroid of, vii. 476
    dilatation of, vii. 477
    discission of, vii. 478
    diseases and injuries of, vii. 473* (Fig.)
    divulsion of, vii. 478
    elongation of, vii. 474
    elongation of infra-vaginal portion, vii. 475
    elongation of supra-vaginal portion of, vii. 476
    enchondroma of, vii. 500
    follicular erosions, vii. 486
    granular erosions of, vii. 486
    hypertrophy, vii. 474
    injuries of, vii. 477
    laceration of, vii. 478
    ovula Nabothi, vii. 486
Uterus, cervix (continued):
    papillary erosions, vii. 486
    senile atrophy, vii. 473
    stenosis of, vii. 477
    syphilitic ulceration of, vii. 476
    ulceration of, vii. 476
  chancre of, ii. 63
  changes in, during pregnancy, ii. 392
  congenital malformations of the, vii. 463* (Fig.)
    abnormal communications, vii. 473
    abnormal plication of the cervical cavity, vii. 473
    absence, vii. 463
    absence or atrophy of the cervix, vii. 465
    atrophy, vii. 464
    classification and nomenclature, vii. 463
    double-mouthed uterus, vii. 473
    double uterus, vii. 470
    faulty development of the uterus, vii. 472
    general etiology, vii. 463
    hernia uteri, vii. 473
    obliquity of the uterus, vii. 473
    one-horned uterus, vii. 466
    premature uterine development, vii. 473
    two-chambered uterus, vii. 469
    two-horned uterus, vii. 467
  congenital malpositions of, vii. 473
  constriction ring, as an impediment to version, vii. 633 (Fig.)
  curetting the, vii. 485, 487
  cylindrical epithelium of, i. 775 (Fig.)
  development of, vii. 463
  didelphys, vii. 470 (Fig.)
  diseases of the, during pregnancy, vi. 18
    headache in, iii. 517
  displacements of, vii. 443* (Fig.)
    Alexander's operation for, vii. 455, 459
    anatomical considerations, vii. 444
    and engorgements, electricity in, ii. 654
    anteflexion, vii. 447
    anteversion, vii. 446
    as a cause of dystocia, iv. 331
    classification of, vii. 445
    congenital, vii. 473
    during pregnancy, vi. 16 (Fig.)
    historical review, vii. 443
    hysterorrhaphy, vii. 455
    in diseases of the Fallopian tubes, iii. 29
    pessaries in, v. 613
    postural treatment of retroversion, vii. 452
    preliminary considerations, vii. 443
    retroflexion with adhesions, vii. 456
    retroversion and retroflexion, vii. 450
    shortening of the round ligaments, vii. 455, 459
    Sims's operation for anteflexion, vii. 449
    treatment, vii. 446
    ventral fixation, vii. 455
  double, vii. 470 (Fig.)
  double-mouthed, vii. 473 (Fig.)
  duplex, vii. 470 (Fig.)

Uterus (continued):
  during menstruation, iv. 726
  dysmenorrhœa in affections of, ii. 557
  endometritis, vii. 481* (Fig.)
  enlargement of, in extra-uterine pregnancy, ii. 777
  epithelioma of the cervix, viii. 561*
  examination of, iii. 417
  extirpation of, for malignant disease, vii. 499
  fibro-cysts of, i. 23
    and ovarian cysts, differential diagnosis, v. 425
  fibroid tumors of, i. 23; vii. 500 (Fig.)
    and ovarian cysts, differential diagnosis, v. 425
    as a cause of dystocia, iv. 339
    diagnosis, vii. 501
    electrolysis in the treatment of, ii. 657; vii. 502
    etiology, vii. 500
    prognosis, vii. 501
    symptoms, vii. 501
    treatment, vii. 501
  fundus of, vii. 563
  glands of, vii. 567
  hernia of, vii. 473
  how to define the size of, by palpation, v. 273
  hyperplasia of, vii. 472
  in early life, vii. 572
  in old age, vii. 573
  incision of, iii. 811
  inertia of, as a cause of dystocia, iv. 331
  inversion of the, iv. 349 (Fig.); vii. 488* (Fig.)
    acute, vii. 489
    chronic, vii. 492
    complicated with a polypus, vii. 493
    continued elastic pressure in the reduction of, vii. 494, 495
    dangers of rapid reduction of, vii. 494
    frequency, vii. 488
    in a multipara, independent of polypus or tumor, vii. 491
    varieties, vii. 488
  involution; subinvolution; superinvolution, viii. 572*
  junction of, with vagina, vii. 563, 564
  lacerated cervix, operations for, vii. 156 (Fig.)
  ligaments of the, vii. 459, 563 (Fig.)
  lymphatic vessels of the, viii. 399
  lyra, vii. 566
  malformations of the, vii. 463 (Fig.)
    as a cause of dystocia, iv. 331
  massage of, iv. 667
  measurements of, vii. 564
  medication of, iv. 688
  mucosa of, ii. 389; vii. 567
    regeneration of, post partum, ii. 393
  muscular layers, vii. 567
  myoma of, v. 80 (Fig.); vii. 500 (Fig.)
  new-growths of the, i. 22; vii. 496* (Fig.)
    benign, vii. 496, 500
    malignant, vii. 497
  normal position of the, vii. 444 (Fig.); viii. 578
  obliquity of, vii. 473 (Fig.)

Uterus (continued):
  one-horned, vii. 466 (Fig.)
  os, vii. 565
    stenosis of, vii. 477
  palmæ plicatæ, vii. 566
  polypi of, vii. 496
  prolapse of the, viii. 578*
    and inversion of, diagnosis between, vii. 493
  removal of, iii. 799
  retraction of, as an impediment to version, vii. 633 (Fig.)
  retroflexion of, vii. 450
    with adhesions, vii. 456
  retroversion of, vii. 450
    pessaries for, v. 615 (Fig.)
    with adhesions, vii. 456
  rudimentary, vii. 464 (Fig.)
  rugæ penniformes, vii. 566
  rupture of, iv. 332 (Fig.)
  sarcoma of, vii. 500 (Fig.)
  scirrhous carcinoma of, i. 778
  septus, vii. 469 (Fig.)
  shape of, vii. 563
  squamous epithelioma of, i. 775
  subinvolution of, viii. 574
  superinvolution of, viii. 577
    electricity in, ii. 654
  supports of the, vii. 459, 563 (Fig.)
  sympathetic nervous supply of, viii. 511
  syphilitic disease of the, vi. 726
  tuberculosis of, vii. 306 (Fig.)
  tumors of the, i. 22; vii. 496 (Fig.)
    removal of, iii. 811
  two-chambered, vii. 469 (Fig.)
  two-horned, vii. 467 (Fig.)
  tympanites of, i. 23
  unicornis, vii. 466 (Fig.)
  wall of, vii. 567
Utricle of membranous labyrinth, ii. 563 (Fig.)
Uva ursi, i. 482
  as an emmenagogue, ii. 676
Uveal tract, iv. 214 (Fig.)
  arteries of, iv. 215
  inflammations of, ii. 147
  microscopical anatomy of, iv. 215
  nerves of, iv. 214
  veins of, iv. 215
Uvula, amputation of, vii. 505
  bifid, vii. 507
  cleft of, ii. 179 (Fig.)
  diphtheria of, ii. 470
  elongation of, vii. 507
  malformations of the, vii. 507
  new-growths of, vii. 507
  relaxed, vii. 504
Uvula and soft palate, vii. 502* (Fig.)
Uvula of cerebellum, viii. 127 (Fig.)
Uvula vesicæ, i. 508
Uvulotomy, vii. 505 (Fig.)
  among the Persians, vii. 505
  hæmorrhage after, vii. 506
  history of, vii. 505
  in Iceland, vii. 505
  painful deglutition after, vii. 506
  performance of, vii. 505

VACCINAL erythema, ii. 721
Vaccination, vi. 479, 483, 486; vii. 509* (Fig.)
  action of disinfectants on the contagion of vaccine lymph, vii. 548
  age at which revaccination should be performed, vii. 514
  age for primary, vii. 516

Vaccination (continued):
  alleged increased general death-rate resulting from, vii. 558
  alleged increased liability to other diseases caused by, vii. 558
  alleged inefficacy of, vii. 556
  amount of lymph obtainable from one heifer, vii. 541
  and small-pox, comparative protection afforded by, vii. 537
  animal, vii. 537
  antisepsis in, vii. 548
  auto-vaccination, vii. 575
  bibliography, vii. 559
  bovine, vii. 537
    collection of lymph, vii. 545
    region to be selected for inoculation, vii. 544
    regulations of German government concerning, vii. 548
    scarificator for, vii. 545
    technique of, vii. 543
  by puncture, vii. 517
  by scarification, vii. 517
  capillary tubes, vii. 547
  care of instruments, vii. 519
  circumstances calling for immediate, vii. 519
  compulsory, vii. 553
  collection of lymph, vii. 545
  conditions upon which its modifying power depends, vii. 529
  contested points in relation to, vii. 528
  crusts, vii. 547
  cultivation of lymph, vii. 551
  degeneration of vaccine, vii. 542
  disinfection in, vii. 548
  displacement of mortality as an argument against, vii. 557
  dry lymph in crusts, vii. 547
    in ivory points, vii. 545
    in powder, vii. 547
    on quills, vii. 547
  duration of protective power of, vii. 537
  effect of climate, vii. 513
  effect of, upon the age-distribution of the mortality from small-pox, vii. 531
  extent to which it is now practised, vii. 519
  health of individual, as affecting, vii. 516
  history of, vii. 509
  human and bovine, comparative results of, vii. 538
  instructions of Local Government Board concerning, vii. 517
  instruments employed, vii. 518
  insusceptibility to, vii. 516
  ivory points, vii. 545
  laws of different countries relative to, vii. 553
    of the United States relative to, vii. 554
  methods of, vii. 517
  moist lymph, vii. 547
  morphology of vaccine lymph, and its artificial cultivation, vii. 551
  necessity of revaccination, vii. 514
  number of insertions, vii. 516
  objections against, vii. 556
  opposition to, vii. 555
  protection afforded by, vii. 513, 522
  quills, vii. 547
  revaccination, vii. 513
  statistics of results, vii. 522
  technique of, vii. 516

Vaccination (continued).
  transmission of other diseases than vaccinia by means of, vii. 540, 557
  vaccinization, vii. 515
Vaccinators, vii. 518 (Fig.)
Vaccinia, ii. 318; vii. 510
  constitutional symptoms of, vii. 511
  definition of, vii. 510
  in equo, vii. 512
  inoculation of, vii. 510
  [illegible] of, i. 283
  relation of, to variola, vii. 511
  spurious eruptions, vii. 511
Vaccinium canadense, vii. 560
  corymbosum, vii. 560
  macrocarpon, vii. 560
  myrtillus, vii. 560*
  oxycoccus, vii. 560
  pennsylvanicum, vii. 560
  vitis Idaea, vii. 560
Vaccinization, vii. 515
Vacuum, viii. 159
Vagina, absence of, vii. 575 (Fig.)
  air cysts of the, vii. 583
  anatomy of, vii. 560
  and uterus, vii. 560* (Fig.)
    accidents following operation for, vii. 574, 579
    as an impediment to marriage, vii. 574
    atresia of the, vii. 573*, 576 (Fig.)
    causes, vii. 573, 577
    diagnosis, vii. 578
    location, vii. 576
    prognosis, vii. 579
    symptoms, vii. 573, 577
    treatment, vii. 574, 578
  blood-vessels of the, vii. 562
  cysts of the, vii. 581*
    containing air, vii. 583*
    containing fluid, vii. 581
  carina, vii. 561
  chancre of, ii. 63
  columns, vii. 561
  communications of, with other cavities, vii. 580
  congenital malformations of the, vii. 575* (Fig.)
    abnormal communications with other cavities, vii. 580
    absence, vii. 575
    atresia, vii. 573, 576
    duplex vagina, vii. 580
    imperforate hymen, vii. 576
    infantile vagina, vii. 581
    inversions of the mucous membrane, vii. 581
    stenosis, vii. 579
    varieties, vii. 575
  development of, vii. 575
  duplex, vii. 580 (Fig.)
  emphysema of the, vii. 583
  examination of, iii. 416 (Fig.)
  fistula of, vii. 580 (Fig.)
  fluid cysts of the, vii. 581
  fornix, vii. 561
  glands of the, vii. 563
  gonorrheal inflammation of, vii. 591
  infantile, vii. 581
  inflammation of, vii. 590
  inversion of mucous membrane of the, vii. 581
  lacerations of, during labor, iv. 348
  lymphatics, vii. 563; viii. 398
  measurements, vii. 561, 658
  occlusion of, iv. 688
  mucous membrane, vii. 561

Vagina (continued).
  ostium, vii. 560
  removal of uterus through, iii. 804
  rugae, vii. 562
  so-called erectile tissue of the, vii. 562
  spasmodic constriction of the, vii. 587
  stenosis of, vii. 579
  subinvolution of the, viii. 577
  syphilitic disease of the, vi. 726
  tampon of the, vii. 584* (Fig.)
    introduction of, vii. 584
    materials for, vii. 584
    removal of, vii. 585
  tamponade of the, vii. 585
  venous plexus surrounding, vii. 562
  wall, vii. 562
Vaginal hernia, iii. 627
Vaginal pregnancy, ii. 775
Vaginalitis, iii. 726
Vaginismus, vii. 587*, 693
  intermittent, vii. 588
  superior, vii. 588
Vaginitis, vii. 590*
  emphysematosa, vii. 583
  in children, vii. 590
  in married women, vii. 591
  in the etiology of condyloma, ii. 261
  in unmarried women, vii. 590
  specific, vii. 591

  on tumors of the spinal cord and its membranes, vi. 589
Ziemssen's double laryngeal electrode, viii. 381 (Fig.)
Zigzag striations of columnæ carneæ in idiopathic anæmia, i. 182
Zinc, viii. 74*
  acetate, viii. 76
  bromide, viii. 75
  butter of, viii. 75
  carbonate, viii. 75
  chloride, viii. 75
    antiseptic efficacy of, i. 254
    as a deodorant, ii. 406
    caustic action of, ii. 6
    germicidal action of, iii. 327
    in antiseptic surgery, i. 265
  cosmetic employment of, ii. 309
  general medicinal properties of compounds of, viii. 74
  in drinking-water, vii. 713
  iodide, viii. 76
  medicinally used compounds of, viii. 75
  nitrate, viii. 76
  oleate, viii. 76
  oxide, viii. 75
  phosphide, v. 642; viii. 76
    as a tonic, vii. 127
  precipitated carbonate of, viii. 75
  spar, viii. 75
  splints, vi. 608
  sulphate, viii. 76
    caustic action of, ii. 6
    germicidal action of, iii. 327
  therapeutics of, viii. 75
  valerianate, viii. 76
Zingiber, iii. 329 (Fig.)
Zinn, zonule of, vi. 348
Zizyphus vulgaris, i. 717; iv. 264
Zona, iii. 645 (Fig.)
  cartilaginea of cochlea, ii. 566
Zona (continued):
  ciliaris, vi. 353 (Fig.)
  radiata or pellucida of the ovum, v. 437, 440 (Fig.)
Zones, epileptiginous, ii. 706
Zonula ciliaris, vi. 348
  injuries of, ii. 801
Zonule of Zinn, vi. 353 (Fig.)
Zoöglœa, vi. 330
Zoögrafting, vi. 458
Zoölogy. See *Biology.*
Zoönerythrin, ii. 248
Zoö-parasites, v. 516
Zoöspores, formation of, viii. 442 (Fig.)
Zoster, iii. 645 (Fig.)
  abdominalis, iii. 647
  anatomical character of the vesicles of, iii. 645
  brachialis, iii. 647
  cervicalis, iii. 647
  corneæ, ii. 295
  course of, iii. 646
  etiology of, iii. 645
  facialis, iii. 647
  lumbalis, iii. 647
  prognosis of, iii. 647
  sacralis, iii. 647
  symptoms of, iii. 646
  thoracalis, iii. 647
  treatment of, iii. 647
Zwenck's pessary, v. 619 (Fig.)
Zygomatic lymphatic glands, viii. 392
Zygomaticus major, anomalies of, v. 35
Zygomaticus minor, anomalies of, v. 35
Zygomycetes, vi. 328
Zygon of a fissure, viii. 155 (Fig.)
Zygospores, vi. 327
Zymogen, ii. 449
Zymosis, ii. 283
  history of theory of, viii. 76
Zymotic diseases, ii. 282; viii. 76*
  classification of, not yet feasible, viii. 79
  etiology of, viii. 76
